SC7 SPECIAL CONSIDERATIONS

Diethylene Glycol

Joshua G. Schier

HISTORY AND EPIDEMIOLOGY

Diethylene glycol (DEG) is a solvent with physical and chemical properties similar to propylene glycol used throughout the chemical industry. Pharmaceutical-grade propylene glycol is a safe and commonly used solvent for water-insoluble pharmaceuticals (Chap. 55). However, unlike propylene glycol, DEG is a potent nephrotoxic and neurotoxic chemical. Substitution of DEG for propylene glycol and other diluents such as glycerin in oral pharmaceutical elixirs has repeatedly caused epidemics of mass poisoning (Chap. 2). This substitution has occurred early in the pharmaceutical manufacturing process due to the intentional mislabeling of DEG as a replacement for the intended pharmaceutical-grade glycerin,⁴² for financial gain⁴⁹ and other reasons, without regard to safety-grade glycerin.¹⁵ As medication-associated DEG mass poisonings have recurred, numerous quality assurance and control guidelines have been developed to identify DEG-contaminated materials. Failure to adhere to these guidelines throughout the pharmaceutical manufacturing and distribution process contributes to this public health problem.⁴⁹ In DEG poisoning, patients develop acute kidney injury (AKI) that can rapidly progress to renal failure and death. Those patients who do not die quickly after exposure, but who develop AKI, often become dialysis dependent and may go on to develop neurological signs and symptoms. These patients may deteriorate further after onset of neurotoxic signs and symptoms and subsequently die.

The metabolism of DEG and the pathophysiology of DEG-associated disease are incompletely understood and most of what is known comes from animal studies. Indeed, very little data are available in humans. Previously, DEG was thought to be metabolized to two ethylene glycol molecules which, when metabolized to glycolic acid and oxalic acid, caused AKI; this theory has been disproven.⁵⁷ Current evidence supports that the terminal DEG metabolite diglycolic acid (DGA) is nephrotoxic. Diglycolic acid appears to be neurotoxic as well based on a single, published case report of poisoning-grade glycerin.⁴⁴ This chapter will provide a brief history and epidemiology of DEG poisoning, describe existing pharmacokinetic and toxicokinetic data collected primarily from animal studies, and then discuss available information on the toxic dose, pathophysiology, clinical manifestations, testing and treatment for DEG poisoning. When specific doses of DEG in the literature were reported in mL/kg, they were converted to g/kg by taking into account the density of DEG (1.118 g/mL) and the concentration. If information on concentration was not provided, then a 100% concentration was assumed. For the reader's convenience, the original dose (if it was in mL/kg) and commensurate DEG concentration are provided following the converted dose in g/kg or mg/kg.

DEG is produced by the condensation of two ethylene glycol molecules forming an ether bond,¹ which yields a compound with a molecular weight of 106 g/mol.^{1,46} It was first identified in 1869 and has been used in industry and manufacturing since 1928.¹ It has found use as an antifreeze, as a finishing agent for wool, cotton, silk, and other fabrics, as well as in dye manufacturing. DEG is chemically inert and has a higher boiling point than ethylene glycol.^{20,58} Its other physical properties are quite similar to ethylene glycol, including a sweet taste.^{20,58} It is often used as an intermediate in the production of polymers, higher glycols, morpholine, and dioxane.³⁵ Its physical properties enable it to serve as an excellent solvent for delivery of water-insoluble substances. Unfortunately, its use as a solvent for various pharmaceuticals intended for human consumption has resulted in the vast majority of reported cases of poisoning.^{6,8,9,12,14,15,17,18,28,32,38,42,50,52,58} In these recurring events, DEG was substituted for a safe and appropriate diluent such as glycerin or propylene glycol. DEG poisoning has also resulted from the intentional addition of DEG to wine as a sweetener^{55,56} or when it was consumed as a substitute for ethanol.⁶⁰ Finally, there are numerous isolated case reports of DEG poisoning resulting from the consumption of DEG-containing products such as radiator fluid or antifreeze,³⁶ brake fluid,⁷ Sterno,⁴³ “fog solution,”¹⁹ cleaning solutions,¹ and wallpaper stripper.³⁴

PHARMACOKINETICS/TOXICOKINETICS

Absorption and Distribution

In rodents DEG is highly (>75%) and almost immediately absorbed after ingestion. It is distributed primarily based on blood flow, with the kidneys receiving the most DEG, followed by the brain, the spleen, liver, and muscles.²⁰ The degree of protein binding and the volume of distribution (Vd) in humans is unknown but the Vd in the rat is approximately 1 L/kg.²⁰ Maximal DEG plasma concentrations occur within 4 hours of ingestion: the ratio of DEG in plasma to red blood cells is 3:2 (approximately 60% of a dose is found in the plasma).^{3,20,58} DEG readily crosses the blood–brain barrier,^{20,58} and concentrations peak in brain tissue (CSF concentration was not reported) within 3 to 4 hours of exposure.²⁰

Metabolism. Existing animal data demonstrate that as much as 40% of an ingested dose may undergo hepatic metabolism with most of that eliminated in the urine.^{20,25,33} Diethylene glycol is metabolized by alcohol dehydrogenase (ADH) to 2-hydroxyethoxyacetaldehyde which is then further metabolized by aldehyde dehydrogenase (ALDH) to 2-hydroxyethoxyacetic acid (HEAA).^{4,57} HEAA is either renally excreted, oxidized to DGA (also known as 2,2-oxybisacetic acid) or converted to 1,4-dioxan-2-one under extremely acidic conditions.⁵⁶ The predominant pathway depends on numerous factors such as dose, degree of kidney function, and acid-base status of the patient.^{4,30,33,57} The DEG ether bond linking the two ethylene glycol molecules is stable and is not hydrolyzed. Ingestion of DEG and subsequent metabolism does not therefore result in ethylene glycol release.^{4,35,57} However, a small amount of ethylene glycol may be formed as an intermediate after formation of 2-hydroxyethoxyacetaldehyde (Fig. SC7–1).⁴ Serum HEAA concentrations peak approximately 4 hours following small DEG ingestions (2 g/kg), but a delayed peak at 8 to 24 hours occurs with larger exposures (10 g/kg) in rodents. Rats which ingest relatively small doses of DEG (2 g/kg) and rats given larger amounts of DEG with coadministration of an ADH blocker (10 g/kg + fomepizole) do not accumulate DGA in their serum over time. Blood DGA concentrations in rats dosed with 10 g/kg of DEG and fomepizole are not significantly different from control rat blood DGA concentrations. Furthermore, DEG elimination half-lives in the two groups dosed with 10 g/kg (one with fomepizole and without) were not significantly different, and almost the entire DEG dose given to the DEG plus fomepizole group was recovered in the urine. This suggests that elimination from the body is mainly controlled by urinary elimination of DEG, rather than by metabolism. Larger doses (10 g/kg) in rat studies, without simultaneous coadministration of an ADH inhibitor, are associated with clinically significant serum DGA concentrations that peak at 24 hours postingestion. If kidney function is impaired, concentrations of both HEAA and DGA continue to climb in a dose dependent manner.³

FIGURE SC7-1 Metabolic pathway for DeG based on previous animal studies and on the results presented in this report. Metabolites in solid boxes have been observed following administration of DeG to animals; those in dashed boxes are theoretical intermediates. Because fomepizole reduced the amount of eG in the urine, its origin is shown as coming from the aldehyde or acid intermediate, rather than from DeG itself. ALDH = aldehyde dehydrogenase. DGA is also known as oxybisacetic acid. (Reproduced with permission from Oxford University Press from Besenhofer LM, Adegboyega PA, Bartels M, et al. Inhibition of metabolism of diethylene glycol prevents target organ toxicity in rats. *toxicol Sci.* 2010;117(1):26.)

Elimination

Animal studies utilizing DEG with radiolabeled carbon report that most (> 60%) of a dose is eliminated within 24 hours of ingestion and almost all (> 90%) within 72 hours.^{33,35} The majority of a DEG dose is eliminated unchanged in the urine (> 60%).^{20,33} The proportion of DEG excreted in the urine increases when compared to metabolites as the dose increases due probably to saturation of hepatic metabolism.^{33,35} This effect persists for approximately 24 hours following exposure. This effect may not be demonstrable beyond 24 hours because either the dose was small enough such that it was rapidly eliminated or because the dose was large enough to induce AKI.³³ As the dose increases, the probability of developing AKI increases, which will result in a decreased elimination of both DEG and its metabolites. Up to 30% of a DEG dose may be eliminated via the kidneys as HEAA.^{3,13,33,57} Most initial work did not either look for or detect DGA, probably due to small exposures in the range of 1.1 g/kg, which did not result in substantial DGA generation.⁵⁷ For those reasons DGA metabolic data was not available until recently.^{3,4} Although both HEAA and DGA are taken up into the liver and the kidneys in a dose-dependent manner, the kidney tissue concentrations of HEAA are correlated directly with peak blood concentrations, but DGA concentrations are not. In fact, kidney tissue DGA concentrations are approximately 100 times greater than peak blood DGA concentrations suggesting much greater accumulation in the kidney.³ This accumulation explains the low concentrations of urinary DGA seen experimentally.⁴ In rodent studies of DGA ingestion limited to 48 hours, DGA is detected in the urine, but at concentrations 50 times lower than HEAA.⁴ However, biologic samples in DEG poisoned humans many days after exposure and in the presence of AKI demonstrated a predominance of urinary DGA concentrations and a relative absence of urinary HEAA.⁴⁸ These findings may be due to a number of different reasons such as the delayed blood peak of DGA when compared with HEAA, the greater time interval from exposure to sampling, which may have afforded a greater likelihood of HEAA metabolism to DGA (compared with experimental animal data), and saturation of kidney tubule cell uptake of DGA. Finally, small amounts of a given DEG dose are eliminated in a dose-dependent fashion via fecal excretion (< 3%) and exhalation (< 7%).^{20,33,35,46} Animal studies also demonstrate that small amounts of DEG radiolabeled carbon is not eliminated but distributed to and collected in certain tissues such as muscle, fat, and skin (< 4% each) and the intestines, liver, and kidneys (< 2% each).^{33,35}

Two studies have reported data on half-lives calculated from serial DEG concentrations. The first reported that oral doses of 6.7 and 13.4 g/kg (6 mL/kg and 12 mL/kg of assumed 100% DEG) result in half-lives of 8 and 12 hours, respectively.⁵⁸ The second report suggests that when animals are given DEG doses of 1.1, 5.5, and 10.9 g/kg (1, 5, and 10 mL/kg of 97.5% DEG), most (64%, 87%, and 91%, respectively) of the dose is eliminated in the first 16 hours after exposure with calculated half-lives of 3 to 4 hours.²⁰ The remainder is then eliminated much more slowly with half-lives ranging from 39 to 49 hours.²⁰

Several rodent studies have reported data on elimination half-lives collected from serial urinary DEG measurements in pharmacokinetic investigations. These same studies have demonstrated that a DEG dose-dependent osmotic diuresis occurs. As the ingested dose increases from 1.1 to 19.6 g/kg (–17.5 mL/kg of > 99% DEG), it induces a fourfold increase in urine production. This effect appears to plateau at approximately 19.6 g/kg (17.5 mL/kg of > 99% DEG).²⁰ DEG appears to undergo zero order kinetics for the first 9 to 18 hours following ingestion. This correlates temporally with the osmotic diuresis which may contribute to this phenomenon.^{20,33} During this time, elimination half-lives range from 6 hours at doses of 1.1 to 5.5 g/kg (1–5 mL/kg of 97.5% DEG) to 10 hours for doses of 10.9 g/kg (10 mL/kg of 97.5% DEG).²⁰ First order kinetics ensue thereafter with elimination half-lives that are dose-dependent and range from 3 to 13 hours.^{3,4,20,33} Based on some animal data, 12 hours may be sufficient to eliminate 94% of a dose assuming an elimination half-life of 3 hours at doses of 1.1 to 5.5 g/kg (1–5 mL/kg of 97.5% DEG).^{20,24} However, several other studies with similar exposures (2 g/kg) suggest that urinary elimination half-lives may be as high as 5 to 6 hours, which suggests that more than 12 hours is needed to eliminate the majority of an similar dose.^{4,20} Half-lives can be prolonged to at least 13 hours in more substantial poisonings (10 g/kg)³ and as kidney function becomes impaired DEG and its metabolites are unable to be excreted effectively, thereby prolonging elimination half-lives further. This information is of importance in determining the appropriate observation period for a suspected or known DEG exposure.

TOXIC DOSE

Rodent studies suggest that doses of up to 2 g/kg are minimally toxic and that doses of approximately 10 g/kg result in significant toxicity.⁴ However, rodents are relatively resistant to the clinical effects of DEG poisoning compared to humans. Human data are limited, established primarily from the history of affected patients from mass poisoning events, and usually represent an estimated cumulative exposure that occurred over a certain time period, rather than a single point of time. The median estimated toxic dose from the 1995 Haitian epidemic was approximately 1.5 g/kg (range, 0.25–4.94 g/kg) (1.34 mL/kg; range, 0.22–4.42 mL/kg of 100% DEG).³⁸ This estimation is similar to the doses reported for the elixir of sulfanilamide outbreak in the United States in the 1930s.⁸ The estimated toxic dose (0.35 g/kg) based on patient recall in the

2006 DEG mass poisoning in Panama was lower than previous events (personal communication, Nestor Sosa, MD). The lower toxic dose in this outbreak may be due in part to an older population with more chronic diseases when compared with other outbreaks that affected younger, presumably healthier persons (unpublished data from author). Postmortem DEG concentrations from an Argentinean outbreak reported a lethal dose ranging from 0.014 to 0.170 mg/kg,^{12,14} although these data were suggested to be inaccurate, possibly by a factor of 1000.⁴⁵ In addition, the analytical testing techniques used in this report may have been subject to error due to cross-reactivity with other metabolites formed as the result of normal postmortem processes.¹⁶ These data also are inconsistent with the fact that polyethylene glycol solutions with trace DEG concentrations yielding average total DEG exposures of 11 mg (range, 2–22 mg) administered for whole bowel irrigation in adults are without adverse effects.⁵⁹ The trace DEG concentrations found in these polyethylene glycol solutions may simply reflect a minor contamination or byproduct produced during the manufacturing process. This issue has not been studied. Quantities far in excess of the Argentinean analysis are estimated to occur in adults from nonprescription health products containing trace amounts of DEG (maximum value, 6.3 mg) currently sold in the United States.⁴⁸ There are no reports of DEG poisoning associated with these products.⁴⁸

In summary, the minimum toxic DEG dose in an acute, single dose exposure is unknown but limited data suggest that single, small total exposures of ≤ 22 mg in an adult are not associated with adverse health effects. Analysis of outbreaks of DEG poisoning suggests that cumulative exposures of as little as 250 mg/kg are associated with illness,³⁸ but the minimum toxic DEG dose may be lower.

The minimum toxic dose of DGA is unknown but ingestion of 100 g in an adult was fatal. The actual toxic dose is probably much less since the patient in this case report vomited immediately after ingestion but still died.⁴⁴

PATHOPHYSIOLOGY

Accumulation of HEAA and DGA in the blood causes a metabolic acidosis that can be prevented by early administration of an ADH inhibitor such as fomepizole.^{3,4} Although there are no published reports examining the efficacy of ethanol to block DEG metabolism, it would be expected to do this also. Inhibition of DEG metabolism with an ADH inhibitor prevents kidney and liver toxicity⁴ and decreases lethality in rodents.⁵⁷ The parent compound DEG does not appear to be toxic based on these same studies.^{4,30,57} Diglycolic acid is likely to be the major if not sole cause of nephrotoxicity in DEG poisoning. Studies with human proximal tubule cells demonstrate that DGA induced cell death is due to necrosis via uptake by a sodium-dicarboxylate-1 transporter, which probably occurs due to its structural similarities to citric acid cycle intermediates. This results in interruption of mitochondrial respiration, leading to energy depletion and ultimately cellular necrosis. This study also suggests that neither DEG nor HEAA cause cellular toxicity in kidney tissue (in vitro proximal tubule cell testing) and that acidemia may enhance DGA toxicity.^{30,31} Elevations in blood urea nitrogen and plasma creatinine concentrations correlate moderately well with elevations in tissue DGA concentrations.⁴ The histopathology of DEG associated nephrotoxicity primarily involves the proximal convoluted tubules as expected and affects the renal cortex where necrosis, hemorrhage and vacuolization can be seen.⁴⁶ Elevations in hepatic aminotransferases can also occur probably due to DEG, HEAA, and DGA accumulation in the liver.^{3,34,46} The spectrum of DEG associated neurotoxicity is complex. Some case reports document primarily demyelinating peripheral neuropathies,^{34,43} but data from the large numbers of patients who received nerve conduction testing from the Panama outbreak and other case reports^{19,50} demonstrate that axonal sensorimotor neuropathy with secondary demyelination is probably the typical clinical course. Only those DEG poisoned patients who develop some degree of AKI seem to be at risk for developing neurotoxicity.^{41,46} The mechanism of neurotoxicity of DEG is unknown but may also be related to DGA (unpublished data from author). The single reported human case of a pure DGA ingestion demonstrated clinical and pathologic findings very similar to DEG poisoning, supporting the notion that DEG poisoning is likely due in great part to DGA.⁴⁴

CLINICAL MANIFESTATIONS

The signs and symptoms of DEG poisoning are dependent on duration of exposure, dose, and other intrinsic host factors such as the presence of comorbidities. Following ingestion, symptoms typical of ethanol intoxication such as lethargy, confusion, “drunkenness,” and altered mental status may begin rapidly and last for several hours.^{5,46} This may be followed by clinical signs and symptoms of a metabolic acidosis including tachypnea and hypernea.^{3,46} Although nausea, vomiting, abdominal pain, diarrhea, headache, and confusion are reported with DEG poisoning,^{7,46} AKI remains the single consistent feature of all cases. This finding manifests over 1 to 3 days following ingestion^{6,9,12,14,18,28,38,42,46,50,52} as a progressive history of oliguria, anuria, or both develops.

In some of the reported DEG mass poisonings, patients have presented in AKI with profound acidosis and acidemia.³⁹ Many of these mass poisonings have occurred in children who received relatively high DEG doses in the form of a

pediatric pharmaceutical such as liquid acetaminophen.^{38,39} In the 2006 Panama mass poisoning, the overwhelming majority of patients were adults who probably ingested smaller doses per unit body weight when compared to child victims of past mass poisonings (although they were probably consumed for a longer period of time). Most of these patients presented to health care facilities with vague gastrointestinal or respiratory symptoms and were found to have AKI.^{42,51} Many subsequently developed bilateral cranial nerve VII paralysis and peripheral extremity weakness, often within several days. Finally, many also rapidly developed encephalopathy, coma, and death in the subsequent 24 to 48 hours.⁵¹ This pattern of AKI followed days later by the appearance of neurological signs and symptoms such as unilateral or bilateral cranial nerve VII (facial nerve) paresis or paralysis, peripheral neuropathy, frank encephalopathy, autonomic nervous system instability, and coma is reported in several case reports, a case series, and two previous mass poisonings.^{1,18,19,43,46,51}

Long-term outcomes among DEG poisoning survivors are not well characterized. Patients who develop AKI that does not improve quickly may become permanently hemodialysis dependent. Those who rapidly recover from their AKI appear to retain normal or at least adequate long-term kidney function. Patients with DEG-associated neurological findings tend to improve over time. In a study that followed DEG poisoning survivors for 2 years following their acute poisoning, delayed-onset renal and neurologic toxicity did not occur.¹¹

DIAGNOSTIC TESTING

The clinician will likely have to rely on a high index of suspicion, a good exposure history and more commonly encountered “routine” testing methodologies including serum electrolytes, blood gas measurements, and renal function studies. Use of the osmol gap calculation has limitations²² but may be helpful in patients with acute ingestions.²³ Although the osmol gap should never be used to exclude the possibility of a toxic alcohol ingestion, if it is very large (> 50) it is unlikely to be due to anything else, especially in the setting of a suspected poisoning. The reader is referred to [Chap. 109](#) for a complete discussion on this topic. Nerve conduction studies may prove helpful in establishing the pattern of neuropathy if present. Otherwise, routine laboratory and diagnostic tests should be used as needed to help evaluate end organ damage.

Although laboratory assays for DEG in whole blood, serum, plasma, and urine are commercially available at specialized toxicology testing laboratories, they are not available in most hospital laboratories. A study conducted during the 2006 Panama DEG mass poisoning demonstrated statistically significant differences ($P < .001$) in urinary DEG concentrations among cases (range, 50–4000 ng/mL) and controls (undetectable); unfortunately the assay used is not available.⁴² Biologic samples collected from the 2006 Panama investigation demonstrated that serum and urine DGA concentrations were significantly associated with case status ($OR > 999$; $P < .0001$).⁴⁸ Diglycolic acid holds promise as a potential biomarker for DEG poisoning, but further work validating the methodology is needed.⁴⁸

TREATMENT

Treatment options include observation, gastrointestinal decontamination, supportive care, administration of an ADH inhibitor therapy, and hemodialysis. There is no evidence of clinical benefit or even reduced bioavailability of DEG following gastric or nasogastric lavage or the administration of oral activated charcoal.²⁶ Nevertheless, given the limited data regarding the role of gastrointestinal decontamination techniques in DEG poisoning, the profound dose-related clinical effects, and the liquid state of the xenobiotic, nasogastric lavage for an individual who presents soon after ingestion for a significant amount may help remove unabsorbed DEG. Since absorption begins immediately after ingestion, the efficacy of lavage after one hour is probably minimal.

Animal evidence suggests that the osmotic diuretic effect of DEG can cause large urinary volume losses in the immediate postexposure period which may not be effectively corrected due to concurrent inebriation. Adequate volume repletion and resuscitation should be performed as soon as possible. The patient should be closely monitored for decreases in urine output, fluid input and output recorded, their function tests closely followed, and appropriate fluid adjustments made for any signs of AKI. There is currently no evidence for forced diuresis; however, all patients should be aggressively hydrated (after appropriate resuscitation if needed) to ensure maintenance of euvolemia and a steady urine output. This is for several reasons, including (1) DEG is primarily eliminated unchanged in the urine via the kidneys, (2) inadequate resuscitation and/or suboptimal hydration beyond the initial fluid resuscitation period may contribute to prerenal azotemia thereby decreasing elimination of unchanged DEG, (3) any impairment in kidney function will result in decreased elimination of unchanged DEG with a corresponding increase in available DEG for metabolism to toxic metabolites such as DGA, and (4) animal studies suggest that when doses associated with adverse health effects (10 g/kg) are given in addition to fomepizole, almost the entire dose is eliminated unchanged in the urine.^{3,30} Careful attention to acid-base status is advised since limited in vitro work with DGA and human proximal tubule cells suggest that acidemia may enhance DGA’s toxicity.^{30,31} Intravenous bicarbonate therapy may be of benefit in treating DEG-associated metabolic acidosis for this reason, but this is unstudied.

Available evidence supports the use of an ADH inhibitor such as fomepizole in suspected or known DEG poisoning to prevent nephrotoxicity, although most of this evidence is from animal studies. This same evidence suggests that the parent compound is not nephrotoxic.^{4,30,57} However, there is no evidence demonstrating that the parent compound is not neurotoxic (the mechanism of DEG associated neurotoxicity is still completely unstudied). Because neurotoxicity seems to only appear following DEG metabolite-associated AKI, the likelihood of the parent compound being neurotoxic seems low. Fomepizole monotherapy for DEG poisoning may be entirely appropriate (similar to other toxic alcohols); however, definitive evidence is lacking. Furthermore, data to guide dosing and duration of administration are also lacking. Considering the aforementioned factors and the current lack of human data confirming safety and efficacy of fomepizole in DEG poisoning, patients presenting soon after (within a few hours) a highly suspected or known moderate to large ingestion of DEG should be started on fomepizole therapy and then urgently hemodialyzed if available. If hemodialysis is not available the patient should be transferred to a facility with that capability. Although the minimal toxic dose is unknown, cumulative exposures at or above 250 mg/kg (the lower limit of the range reported in the Haiti mass poisoning) should be considered potentially life threatening. A single report documented higher prehemodialysis and lower posthemodialysis concentrations of DEG suggesting that it is cleared by hemodialysis, although the gradient was relatively small (0–1.6 mg/dL).⁷ Nevertheless, the volume of distribution and molecular weight of DEG suggest that hemodialysis should be effective.^{20,46} The endpoint of fomepizole therapy or need for additional rounds of dialysis is unclear, but the relatively new commercial availability of techniques for the determination of whole blood, plasma, serum and urine DEG concentrations with careful attention to acid-base status should be helpful in guiding therapy. Considering the lack of fomepizole data in DEG poisoning, dosing should be comparable with the treatment regimens for the other toxic alcohols (Antidotes in Depth: A30).

Exposures to amounts less than those known to be associated with poisoning present management dilemmas. The following sections consist of suggested guidelines which may need to be modified depending on the individual situation. In all exposures, a toxicologist should be consulted as the circumstances surrounding the exposure are invariably different and may affect management.

Outbreak-derived toxic doses of DEG are not reliable measures for excluding poisoning. Patients with a reliable history of a minimal ingestion, such as an unintentional sip of a low concentration DEG containing product, are unlikely to be at risk for toxicity. Those adult patients with slightly larger DEG ingestions with relatively low concentrations liquids (< 10%) such as exposures consisting of more than a sip but less than a “mouthful” can be considered for careful observation alone, as long as it is coupled with serial chemistries and blood gas measurements to rapidly identify onset of renal function and acid-base abnormalities. Although the true minimum toxic dose of DEG is unknown, an example of the aforementioned situation might involve an unintentional ingestion of 30 mL (mouthful) of a 5% DEG product by volume in an adult. This is approximately 1.5 mL of DEG which is equivalent to about 1.7 g, which in an 80-kg adult is about 21 mg/kg. The lower end of the estimated toxic dose range in Haiti was 250 mg/kg, which is more than 10 times higher (1090% increase). Therefore careful observation might be reasonable in this situation if you believed you had correct values for the dose and product concentration and there were no other potential risk factors for DEG-associated illness (eg, preexisting renal disease). Such an exposure in a 3 year-old child weighing 16 kg would yield a dose of 110 mg/kg, an exposure of greater concern that might warrant more aggressive treatment. Unfortunately, ascertainment of the true volume ingested and product concentration may be difficult, which contributes to the problem of estimating risk based on patient history.

Patients with signs or symptoms of alcohol intoxication, but who did not consume ethanol should be suspected of having a potentially life threatening DEG ingestion and treated as discussed in the previous section. Asymptomatic patients with ingestions beyond the “unintentional sip or taste” should probably be observed for at least 24 hours regardless of therapy offered. Serial laboratory determinations should be obtained and evaluated for at least 24 hours following exposure based on what is known of DEG toxicokinetics.

Fomepizole monotherapy (without hemodialysis) can be considered at the discretion of the attending physician and consulting toxicologist or poison center, as emerging evidence suggests that fomepizole can prevent nephrotoxicity. However, if the decision to use fomepizole monotherapy is made, the physician should remember that, albeit unlikely, the safety and efficacy of fomepizole monotherapy in DEG poisoning is not yet established, thereby necessitating that the risks be explained to the patient.

Unless laboratory testing documents a minimal or nonexposure, the patient’s clinical, acid-base, and kidney function status should probably be followed for at least 24 hours for evidence of DEG poisoning. For patients receiving fomepizole, this 24 hour period should begin 12 hours following the last dose of fomepizole. If signs and symptoms of nephrotoxicity begin to appear, then fomepizole should be given and the patient hemodialyzed.

For those patients presenting to health care facilities with a metabolic acidosis, oliguria or anuria within 24 to 36 hours of an DEG ingestion, fomepizole should be given and emergent hemodialysis should be performed, regardless of the patient’s acid-base and electrolyte status. This suggestion is based in part on animal studies showing that serum DGA concentrations peak at 24 hours following ingestion, DGA sequesters in kidney tissue, it is nephrotoxic,^{3,30} and half-lives increase with larger doses.³ Early presentation to health care facilities (< 10 hours from ingestion) and aggressive treatment (gastrointestinal decontamination, fomepizole, and hemodialysis) appeared to be associated with better outcomes in the

five reports in which fomepizole or ethanol was administered for DEG exposure.^{1,5,7,19,43} In one of these cases, a 15 year-old girl who was witnessed to ingest approximately 22.4 g of DEG (patient's weight was not reported) was managed with orogastric lavage and early (< 3 hours) fomepizole therapy alone; the patient had a good outcome with no renal or neurological dysfunction (other than inebriation).⁵ For those patients presenting later than 36 to 48 hours after a DEG ingestion with the aforementioned signs and symptoms, fomepizole and hemodialysis should be considered, but may be too late to be beneficial with regard to removal of DEG and toxic metabolites. However, it may be of value with regard to electrolyte imbalances and or AKI.

Although there are no published reports examining the efficacy of ethanol to block DEG metabolism, it is expected to act similarly to fomepizole. Hence, it may be an alternative therapy if fomepizole and hemodialysis are unavailable and a rapid transfer to another hospital is not possible.

SUMMARY

- Patients with suspected or known exposures to DEG present a diagnostic and therapeutic challenge.
- Emerging work shows that the DEG metabolite DGA, and not the parent compound, is nephrotoxic.
- Alcohol dehydrogenase inhibitor therapies such as fomepizole have a role in treating DEG poisoning, but urgent hemodialysis is still indicated for substantial ingestions.
- Diethylene glycol poisoned patients who develop AKI are at risk for severe neurotoxicity.
- The etiology of DEG associated neurotoxicity is unclear. Diethylene glycol ingestion should be suspected in patients presenting with AKI and neurological signs and symptoms such as cranial nerve VII paresis or paralysis, or extremity weakness consistent with a peripheral neuropathy.

A30 ANTIDOTES IN DEPTH

Fomepizole

Mary Ann Howland

INTRODUCTION

Fomepizole, a competitive inhibitor of alcohol dehydrogenase (ADH), prevents the formation of toxic metabolites from ethylene glycol and methanol. It may also have a role in halting the disulfiram–ethanol reaction and in limiting the toxicity from a variety of xenobiotics that rely on ADH for metabolism to toxic metabolites. In addition, as both an inducer and an inhibitor of certain cytochrome P450 CYP enzymes, the presence of fomepizole may lead to drug interactions.

HISTORY

In 1963, Theorell described the inhibiting effect of pyrazole on the horse ADH nicotinamide adenine dinucleotide (NAD⁺) enzyme–coenzyme system.^{70,89} Pyrazole blocked ADH by complexation, and the administration of pyrazole to animals poisoned with methanol and ethylene glycol improved survival.⁹⁰ However, pyrazole also inhibited other liver enzymes, including catalase and the microsomal ethanol oxidizing system.⁶² Additional adverse effects of pyrazole administration resulted in bone marrow, liver, and kidney toxicity, and these effects increased in the presence of ethanol and methanol.⁷⁴ These factors led to the search for less toxic compounds with comparable mechanisms of action.

In 1969, Li and Theorell found that both pyrazole and 4-methylpyrazole (fomepizole) inhibited ADH in human liver preparations,⁶¹ and studies in rodents found that fomepizole, unlike pyrazole, was relatively nontoxic regardless of the presence or absence of ethanol.¹³ Subsequent studies of fomepizole in monkeys and humans poisoned with methanol and ethylene glycol confirmed both the inhibitory effect and relative safety of fomepizole.^{19,20,74}

PHARMACOLOGY

Chemistry

Fomepizole has a molecular weight of 82 Da, and a pKa of 2.91 at low concentrations and a pKa of 3.0 at high concentrations. The free base is used in the United States, whereas the salts are used in Europe. The free base is chemically equivalent to the chloride and sulfate salts at physiologic pH.²⁴

Mechanism of Action

Fomepizole works by being a potent inhibitor of ADH thereby blocking the metabolism of methanol and ethylene glycol to their respective toxic metabolites.

Values for K_m have been estimated for the toxic alcohols and the K_i with fomepizole. The smaller the K_m , the higher the affinity of the substrate (alcohol) for the enzyme, and the lower the concentration of the substrate to achieve saturation of 50% of the enzyme. Studies in monkey and human liver tissue demonstrate that fomepizole is a competitive inhibitor of alcohol dehydrogenase.^{65,82} In monkey liver, fomepizole demonstrated very similar K_i s for both ethanol and methanol at 7.5

and 9.1 $\mu\text{mol/L}$, respectively.⁶⁵ The affinity was 10 times higher when human liver was used.⁸¹ Studies in monkeys demonstrate that a fomepizole concentration of 9 to 10 $\mu\text{mol/L}$ (0.74–0.8 $\mu\text{g/mL}$) is needed to inhibit the metabolism of methanol to formate.^{13,74} In human liver, the concentration needed to achieve inhibition is about 0.9 to 1 $\mu\text{mol/L}$.^{61,81} The most recent trial using intravenous (IV) fomepizole attempted to maintain a serum fomepizole concentration above 10 $\mu\text{mol/L}$. Current dosing calls for a serum fomepizole concentration of 100 to 300 $\mu\text{mol/L}$ to ensure a margin of safety.¹

CYP2E1 oxidizes ethanol and a number of other xenobiotics, including acetaminophen, carbon tetrachloride, nitrosamines, and benzene to toxic metabolites. Fomepizole, like ethanol and isoniazid, induces CYP2E1 in rat liver and kidney, but not in the lung, through a posttranscriptional mechanism via stabilization and not involving increased messenger RNA.⁷⁶ However, when fomepizole is present, CYP2E1 is inhibited. It is not until after fomepizole is eliminated that the consequences of induction are manifest.^{16,95,96} In hepatocyte culture, fomepizole stabilizes and maintains the induced metabolic activity of the isoenzyme for about one week.⁹⁷

Pharmacokinetics

The volume of distribution of fomepizole is about 0.6 to 1 L/kg; it is metabolized to 4-carboxypyrazole, an inactive metabolite that accounts for 80% to 85% of the administered dose.^{71,76} In healthy human volunteers, oral doses of fomepizole are rapidly absorbed and demonstrate saturation and nonlinear kinetics.^{44,67,76} The K_m was estimated to be 75 $\mu\text{mol/L}$ in two studies, and 0.94 $\mu\text{mol/L}$ at a dose of 15 mg/kg to 2.49 $\mu\text{mol/L}$ at a dose of 7 mg/kg in the two most recent analyses, although the reason for the discrepancy is not known.^{44,67,68,76} First-order kinetics were exhibited at concentrations below the K_m , whereas zero-order elimination occurred at concentrations 100% to 200% of the K_m .⁴⁴ Thus, elimination of fomepizole at doses of 10, 20, 50, and 100 mg/kg was 3.66, 5.05, 10.3, and 14.9 $\mu\text{mol/L/h}$, respectively.⁴⁴ Classical Michaelis-Menten kinetics would predict that the elimination rate should be comparable at the two higher doses. The authors speculate that the differences are attributable to the existence of other metabolic pathways with different affinities that predominate at different fomepizole concentrations. Following multiple doses, the elimination of fomepizole increases at 36 to 48 hours, most likely because of autoinduction.⁷⁶ After 96 hours fomepizole elimination apparently changed to first order elimination with a half-life of 1.5 to 2 hours, from zero order elimination. At a single dose of 20 mg/kg, the apparent half-life of fomepizole calculated from the linear portion of the curve was 5.2 hours and occurred when serum concentrations were less than 100 $\mu\text{mol/L}$. Peak concentrations after oral administration were achieved within 2 hours and were 132, 326, 759, and 1425 $\mu\text{mol/L}$ following 10, 20, 50, and 100 mg/kg doses, respectively. Every increase of 10 mg/kg in the oral dose of fomepizole raised the serum concentration 130 to 160 $\mu\text{mol/L}$.⁴⁴ The renal clearance was low (0.016 mL/min/kg), and only 3% of the administered dose was excreted unchanged in the urine.⁴⁴

In the two most recent pharmacokinetic studies in healthy volunteers, oral administration produced similar serum concentrations to IV fomepizole.^{67,76} The pharmacokinetics of IV fomepizole were studied in 14 patients being treated for ethylene glycol toxicity.⁵² A mean peak concentration of 342 $\mu\text{mol/L}$ (200–400 $\mu\text{mol/L}$) was achieved following a loading dose of 15 mg/kg (183 $\mu\text{mol/kg}$).^{71,86} A significant weakness of the study involving toxicokinetic data is that the effect of simultaneous serum ethanol concentrations was not analyzed. The lowest serum fomepizole concentration of 105 $\mu\text{mol/L}$ was present at 8 hours after the loading dose. The rate of elimination was determined to be zero order at 16 $\mu\text{mol/L/h}$ compared with a first-order elimination half-life of 3 hours during hemodialysis. Other authors have reported similar fomepizole clearances (12.99 $\mu\text{mol/L/h}$).²¹ A recent pharmacokinetic analysis in patients poisoned with methanol or ethylene glycol demonstrated a mean peak fomepizole concentration of 226 $\mu\text{mol/L}$ (19 $\mu\text{g/mL}$), an apparent half-life of 14.5 hours (in the presence of methanol or ethylene glycol), and an apparent half-life of 40 hours in the presence of ethanol, and methanol or ethylene glycol. In the sole death, hepatic tissue contained 12 $\mu\text{g/g}$ of fomepizole, even when the serum concentration was less than 1 $\mu\text{g/mL}$ (12 $\mu\text{mol/L}$).⁹³

The hemodialysis clearance of fomepizole ranges from 50 mL/min to 137 mL/min.^{30,51} An analysis using determinations of dialysis fluid revealed an extraction ratio of approximately 75% and a dialysance of 117 mL/min, which was very similar to a simultaneous ethylene glycol determination.³⁰ The dialysance was similar to urea in a pig model and suggests no significant protein binding of fomepizole.⁴⁵

The pharmacokinetic interactions between fomepizole and ethanol were studied in a double-blind crossover design in healthy human volunteers.⁴⁹ Fomepizole was given orally in doses of 10, 15, and 20 mg/kg 1 hour prior to oral ethanol at 0.5 to 0.7 g/kg as a 20% solution in orange juice. Fomepizole decreased the elimination rate of ethanol by approximately 40%, from 12 to 16 mg/dL/h to about 7 to 9.5 mg/dL/h. When IV fomepizole was administered at 5 mg/kg over 30 minutes and ethanol was administered orally at doses to achieve a concentration of 50 to 150 mg/dL for 6 hours beginning at the end of the fomepizole infusion, the elimination of fomepizole was decreased by approximately 50%.⁴⁹ This decrease occurred without a change in the amount or fraction of unchanged fomepizole appearing in the urine. The authors suggested that the ethanol probably inhibited the metabolism of fomepizole to 4-carboxypyrazole. A single low dose of fomepizole given to humans had a maximal effect on ethanol metabolism at 1.5 to 2 hours.¹² Thus, ethanol and fomepizole mutually inhibit the

elimination of the other, thereby maintaining higher serum concentrations than otherwise expected.^{66,72} Methanol also decreases the elimination of fomepizole by approximately 25% in the monkey.⁷⁴

ROLE IN METHANOL TOXICITY

In Vitro and Animal Studies

Studies using human livers demonstrate the inhibitory effect of fomepizole on alcohol dehydrogenase.⁸¹ Studies in monkeys, the animal species that most closely resembles humans in metabolizing methanol, also clearly demonstrate the inhibitory effect of fomepizole in preventing the accumulation of formate.^{11,74,75}

Human Experience

The two largest fomepizole case series to date involved 11 and 8 patients, respectively, who were given IV fomepizole in the approved US dosing regimen.^{18,20,39} Following administration, formate concentrations in all patients fell, and the arterial pH increased.²⁰ Case reports demonstrate similar findings.^{21,32,35}

Effect on Methanol and Formate Concentrations

Methanol exhibits dose-dependent kinetics.⁴⁸ At low doses (0.08 g/kg), which achieve serum concentrations of about 10 mg/dL, methanol elimination is first order, with a half-life of about 2.5 to 3 hours.^{52,55} In concentrations of approximately 100 to 200 mg/dL, methanol exhibits zero order kinetics and is eliminated at about 8.5 to 9 mg/dL/h in untreated humans⁵⁰ and 4.4 to 7 mg/dL/h in untreated monkeys.^{28,78} When monkeys were given 3 g/kg of methanol with resultant serum concentrations of about 500 mg/dL, the elimination of methanol exhibited apparent first-order kinetics. This alteration is likely caused by the greater contribution of other first-order pathways, such as pulmonary and urinary elimination, which may account for a greater fraction of the total body clearance under these circumstances.⁴⁸ Once fomepizole was administered, the elimination of methanol became first order in humans, and the half-life of methanol was about 54 hours.^{20,39} When the metabolism of methanol to formate is blocked, formate is eliminated with a half-life dependent on dose and with an uncertain effect of folate and bicarbonate therapies. When formate was administered to monkeys in the absence of methanol, formate half-life was 30 to 50 minutes.²⁵ In monkeys given methanol followed by fomepizole, the formate concentrations decreased by more than 80% in 2 hours.¹¹ An analysis of formate concentrations in six patients with methanol poisoning treated with fomepizole, folate, and sodium bicarbonate revealed a formate half-life of 235 ± 83 minutes.⁵³ A more recent analysis involving eight patients with methanol poisoning treated with fomepizole and sodium bicarbonate revealed a formate half-life of 156 minutes.³⁹

ROLE IN ETHYLENE GLYCOL TOXICITY

In Vitro and Animal Studies

Monkeys given 3 g/kg of ethylene glycol intraperitoneally recovered without treatment, whereas those given 4 g/kg died without therapy. All those given 4 g/kg of ethylene glycol with fomepizole survived.²⁵

Human Experience

The first three patients treated with oral fomepizole improved clinically and tolerated the therapy.⁴ Subsequent case reports and case series using fomepizole orally or IV, with or without hemodialysis, also demonstrated the effectiveness of fomepizole in preventing glycolate accumulation.^{5,14,19,33,36,38,51,77,80,86}

Effect on Ethylene Glycol and Glycolate Concentrations in Humans

Kidney function is essential in the elimination of ethylene glycol. With normal kidney function, the half-life of ethylene glycol is about 8.6 hours.⁸⁶ Based on pooled human data, the half-life of ethylene glycol after alcohol dehydrogenase is blocked by fomepizole is about 14 to 17 hours in patients with normal kidney function, and about 49 hours in patients with impaired kidney function.^{4,36,60,86} Based on a limited number of determinations, the renal clearance of ethylene glycol averaged 31.5 mL/min during the first 2 days; the corresponding creatinine clearance was 112 mL/min, and estimated total body clearance during fomepizole therapy was 57 mL/min.⁵ These calculations suggest that the renal clearance of ethylene glycol accounted for only 55% of estimated total body clearance. In a study where neither kidney function was defined nor the amount of glycolate excreted unchanged by the kidneys described, glycolate had a mean half-life of 10 ± 8 hours in patients treated with fomepizole before hemodialysis, and a mean half-life of less than 3 hours during hemodialysis.^{46,54,77}

ROLE IN TOXICITY FROM DISULFIRAM AND OTHER XENOBIOTICS

Fomepizole successfully terminated the adverse reactions resulting from the use of disulfiram administered to volunteers pretreated with a small dose of ethanol, the adverse reaction occurring in a chronic alcoholic surreptitiously given disulfiram by his wife, and in two patients who intentionally ingested ethanol along with an overdose of disulfiram.^{63,84} Pretreatment with oral fomepizole was also successful in preventing the facial flushing and tachycardia typically associated with ethanol administration in ethanol-sensitive Japanese volunteers.^{42,43}

Limited animal studies and a few case reports suggest that fomepizole may be effective in limiting the toxicity secondary to diethylene glycol, triethylene glycol, and 1,3-difluoro-2-propanol.^{9,14,31,85,91} The role of fomepizole in overdoses secondary to 2-butoxyethanol (ethylene glycol monobutyl ether, butyl Cellosolve) is unclear,⁴¹ but fomepizole may be useful if administered within several hours of ingestion and before rapid metabolism of butoxyethanol to butoxyacetic acid occurs.^{69,79} Isopropanol is probably metabolized at least in part by alcohol dehydrogenase, but fomepizole therapy is not indicated, as this intervention would prolong the metabolism of isopropanol to acetone.^{1,56}

COMPARISON TO ETHANOL

Ethanol has been used for many years to inhibit the metabolism of methanol and ethylene glycol to their respective toxic metabolites.^{34,92} Although very inexpensive, ethanol has many disadvantages, compared to fomepizole.^{7,58,94} Ethanol causes central nervous system depression that is at least additive to that of the methanol or ethylene glycol, and dosing difficulties occur as a result of the rapid and often unpredictable rate of ethanol metabolism (Antidotes in Depth: A31).^{7,8,94} Fomepizole has the advantage of being a very potent inhibitor of alcohol dehydrogenase without producing CNS depression. Fomepizole dosing is much easier and does not require therapeutic monitoring of its serum concentration. Limited adverse effects of fomepizole include local reactions at the site of infusion when concentrations exceeding 25 mg/mL are used, nausea, dizziness, anxiety, headache, rash, transiently elevated aminotransferases, and eosinophilia. Fomepizole is preferred to ethanol for all of the above reasons. Ethanol should be used only when fomepizole is not readily available.^{59,87}

ADVERSE EFFECTS AND SAFETY ISSUES

Retinol dehydrogenase, which is responsible for converting retinol to retinal in the eye, is an isoenzyme of ADH. As such, it was essential to study whether fomepizole would inhibit this enzyme and produce retinal damage.^{74,75} Studies in several animal species demonstrated that fomepizole has limited toxicity, with no ophthalmic toxicity.¹¹ Two of the largest case series and two recent case reports confirm the lack of retinal toxicity with fomepizole and demonstrate the reversibility of methanol-induced visual toxicity when patients are treated with fomepizole and hemodialysis before permanent ophthalmic damage developed.^{19,20,29,88}

The LD₅₀ (median lethal dose for 50% of test subjects) of fomepizole in mice and rats is 3.8 mmol/kg after IV administration, and 7.9 mmol/kg following oral administration.⁶⁴ An oral placebo-controlled, double-blind, single-dose, randomized, sequential, ascending-dose study was performed in healthy volunteers to determine fomepizole tolerance at 10 to 100 mg/kg.⁴⁸ There were no adverse effects in the 10 and 20 mg/kg groups, whereas at 50 mg/kg, three of four subjects experienced slight to moderate nausea and dizziness within 2.5 hours of fomepizole administration. All subjects reported comparable symptoms at 100 mg/kg, which lasted for 30 hours in one individual without vital sign or laboratory abnormalities. The most common adverse effects of the use of fomepizole reported by the manufacturer (in a total of 78 patients and 63 volunteers) were headache (14%), nausea (11%), and dizziness, increased drowsiness, and bad or metallic taste (6%).¹ Other less commonly observed adverse effects include phlebitis, rash, fever, and eosinophilia. A case report of a patient severely poisoned with ethylene glycol describes a temporal association between IV fomepizole administration during hemodialysis and the development of bradycardia and hypotension. However, this patient was severely acidemic, and when the patient received the fomepizole postdialysis no such adverse effects were noted.⁵⁷ Divided daily doses of fomepizole up to 20 mg/kg for 5 days have been administered without any demonstrable toxicity.⁷³ The most common laboratory abnormality after fomepizole administration is a transient elevation of aminotransferase concentrations, which was reported in 6 of 15 healthy volunteers.⁴⁷ In the two largest case series of patients treated with fomepizole for toxic alcohol poisoning, there were no adverse events classified as “definitely” or “probably” related to fomepizole.^{19,20} Fomepizole safety and effectiveness in pediatric patients have not been established, but it has been used successfully in children who have ingested ethylene glycol and methanol.^{6,15,17,22,26,27,37,93}

PREGNANCY AND LACTATION

Fomepizole is pregnancy category C and thus should be used when clearly indicated. It is not known whether fomepizole is excreted into breast milk.

DOSING AND ADMINISTRATION

The loading dose of fomepizole is 15 mg/kg IV, followed in 12 hours by 10 mg/kg every 12 hours for 4 doses. If therapy is necessary beyond 48 hours, the dose is then increased to 15 mg/kg every 12 hours, for as long as necessary. This increase is recommended because fomepizole stimulates its own metabolism.⁷⁶ Patients undergoing hemodialysis require additional doses of fomepizole to replace the amount removed during hemodialysis.

The manufacturer recommends dosing fomepizole every 4 hours during hemodialysis.¹ Fomepizole should be administered at the beginning of hemodialysis if the last dose was more than 6 hours earlier. At the completion of hemodialysis, administer the next scheduled dose if more than 3 hours have transpired, or one-half of the dose if 1 to 3 hours have passed. Then continue with every 12-hour dosing.

Fomepizole must be diluted in 100 mL of 0.9% sodium chloride solution or 5% dextrose in water (D₅W) prior to IV administration, and then infused over 30 minutes to avoid venous irritation and thrombophlebitis. Once diluted, fomepizole remains stable for 24 hours when stored in the refrigerator or at room temperature.¹

Fomepizole therapy should be continued until the methanol or ethylene glycol is no longer present in sufficient concentrations to produce toxicity. Although these concentrations are not precisely known, 25 to 50 mg/dL of either ethylene glycol or methanol is a conservative estimate that may need to be lowered in the presence of acid–base disturbances.^{1–3}

The threshold concentrations for hemodialysis of methanol or ethylene glycol can be based on measurements when analyses can be done in a timely fashion. The duration of fomepizole therapy in the absence of hemodialysis can be estimated based on the assumption of half-life of the toxic alcohol when blocked with fomepizole. The half-life of methanol is approximately 54 hours in the presence of fomepizole.¹⁴ The half-life of ethylene glycol in the presence of fomepizole is approximately 14 to 17 hours in patients with normal kidney function, and 49 hours in patients with impaired kidney function.^{4,38,86}

The need for hemodialysis is based on the presence of toxic metabolites inferred by the presence of metabolic acidosis and end-organ damage; the ability of the kidney to eliminate ethylene glycol and glycolic acid, and formate, the risk benefit of hemodialysis, and the length of time to remain hospitalized for elimination of the remaining methanol and ethylene glycol.^{40,83}

FORMULATION AND ACQUISITION

Fomepizole is marketed as Antizol injection by Paladin Labs (Dover, DE; originally by Orphan Medical) in 1.5 mL vials of 1 g/mL. It is now also available generically by various manufacturers. Temperatures of less than 77°F (25°C) cause the contents of the fomepizole vials to solidify. Warming reliquesfies the product without adversely affecting its potency.

SUMMARY

- Fomepizole is a potent competitive inhibitor of ADH that is useful in inhibiting the metabolism of methanol, ethylene glycol, and other xenobiotics that use ADH in the formation of toxic metabolites.
- Once ADH is blocked, the decision to use hemodialysis depends on how much damage has occurred to the organs of elimination, and how well the body can eliminate both the parent compound and the toxic metabolites formed prior to fomepizole administration.
- Fomepizole appears to be safe and, although it has been used successfully orally, only an IV dosing regimen is approved and available.
- Fomepizole is more costly than ethanol, but its many advantages over ethanol, including the ability to often deliver care outside an intensive care unit, make fomepizole the preferred antidote in most circumstances.
- Ethanol might be preferred in a mass casualty situation until sufficient supplies of fomepizole could be procured.

A31 ANTIDOTES IN DEPTH

Ethanol

Mary Ann Howland

INTRODUCTION

Ethanol is used therapeutically as a competitive substrate for xenobiotics metabolized by alcohol dehydrogenase, thus limiting the bioactivation of those xenobiotics to toxic metabolites. Methanol and ethylene glycol are potentially lethal xenobiotics metabolized by this pathway.^{11,12} Ethanol may also inhibit the metabolism of short chain polyethylene glycols, such as di- and triethylene glycol,⁵³ and possibly compete with monofluoroacetate and fluoroacetamide for binding to the tricarboxylic acid cycle. Ethanol also affects the cytochrome P450 CYP enzyme system, especially CYP2E1, for which it has biphasic properties as an inducer and an inhibitor similar to fomepizole and isoniazid. The competitive relationship of ethanol with potentially toxic xenobiotics can be used to therapeutic advantage, but the effect of ethanol on the CYP system often leads to unwanted drug interactions and pharmacokinetic tolerance after several days of administration.

HISTORY

Ethanol has been used as an antidote for methanol poisoning since the 1940s and for ethylene glycol since the 1960s.²

PHARMACOLOGY

Mechanism of Action

Ethanol works as a competitive substrate for alcohol dehydrogenase, inhibiting the metabolism of xenobiotics like methanol and ethylene glycol that use this enzyme.

Affinity for Alcohol Dehydrogenase

The dose of ethanol necessary to achieve competitive inhibition depends on the relative concentrations of the toxic alcohols and their affinity for the enzyme. An affinity constant, K_m , is used to express the degree of affinity: the lower the K_m value, the stronger the affinity. The following equates mmol or mg for alcohols: 1 mmol ethanol equals 46 mg, 1 mmol methanol equals 32 mg, and 1 mmol ethylene glycol equals 64 mg. A millimolar concentration means mmol/L. A summary of in vitro experiments using human liver cells demonstrated a K_m of 30 mM for ethylene glycol, 7 mM for methanol, and 0.45 mM for ethanol.^{29,42,43} This means that the molar affinity of ethanol for alcohol dehydrogenase is 67 times that of ethylene glycol and 15.5 times that of methanol. Studies in methanol-poisoned monkeys revealed that when ethanol was administered at a molar ethanol-to-methanol ratio (E:M) of 1:4, the metabolism of methanol was reduced by 70%; at a 1:1 E:M ratio, metabolism was reduced by greater than 90%.³² In these experiments, the dose of methanol was kept constant at about 1 g/kg (31 mmol/kg), whereas the dose of ethanol was varied. Although the serum methanol concentration was not measured, a calculation using this dose and a volume of distribution (Vd) of 0.6 L/kg would predict a serum concentration of about 166 mg/dL. Even in molar ratios as high as 1:8, methanol did not inhibit ethanol metabolism. When ethylene glycol and methanol are administered together in a 0.5:1 molar ratio, ethylene glycol did not inhibit methanol metabolism.³² When compared with methanol smaller amounts of ethanol are required to block the metabolism of ethylene glycol, as the affinity of ethylene glycol for alcohol dehydrogenase is less than that of methanol.^{22,29,42,43,45,51} Most authors^{1,22,51} recommend either a serum ethanol concentration of 100 mg/dL, or at least a 1:4 molar ratio of ethanol to methanol or ethylene glycol,

whichever is greater. Using this ratio, 100 mg/dL (~ 22 mmol/L) of ethanol protects against 88 mmol/L (286 mg/dL) of methanol or 88 mmol/L (546 mg/dL) of ethylene glycol. Inhibiting the metabolism of methanol and ethylene glycol impedes the formation of toxic metabolites and prevents the development of metabolic acidosis.^{13,16,21,51} After this toxic metabolic pathway is blocked with ethanol, renal, pulmonary, and extracorporeal routes of toxic alcohol removal become the sole mechanisms for elimination.

PHARMACOKINETICS

Ethanol administered orally is rapidly absorbed and achieves peak concentrations in about 1 to 1.5 hours.^{8,15,30,52} The amount of ethanol absorbed after oral administration is highly variable and dependent on a number of factors, such as ethanol dose, fasting, nutritional status, accelerated gastric emptying, gender, genetics, chronic alcohol use, lean body mass, and increasing age, as well as the presence of certain H₂-receptor antagonists.^{6,9,15,25,27,37,54,57} Sufficient concentrations are generally achieved when 0.8 g/kg of ethanol is given orally over 20 minutes.^{6,8,9,15,27,52}

Given that the Vd for ethanol is approximately 0.6 L/kg,^{10,58} the loading dose of ethanol is obtained by the following formula:

$$\begin{aligned}\text{Loading dose} &= C_p \times V_d \\ &= 1 \text{ g/L (100 mg/dL)} \times 0.6 \text{ L/kg} \\ &= 0.6 \text{ g/kg} \\ C_p &= \text{plasma concentration which is comparable} \\ &\quad \text{to the serum concentration}\end{aligned}$$

For a 70 kg person, the loading dose would be 42 g (70 kg × 0.6 g/kg) of ethanol, or 420 mL of 10% V/V (volume-to-volume) ethanol. This calculation assumes that the specific gravity of ethanol is 1 g/mL. However, a 0.8 g/kg or 8 mL/kg loading dose of a 10% ethanol solution is recommended in order to provide a margin of safety because of the variabilities in Vd and the ongoing metabolism that occurs during administration.^{26,44} The intravenous (IV) loading dose should be administered over 20 to 60 minutes, as tolerated by the patient. The 10% ethanol concentration is preferable to the 5% concentration to limit the volume of fluid administered. It is also preferred over the more concentrated solutions to limit local venous irritation and avoid postinfusion phlebitis. Because of the free water content and significant hypertonicity of the 10% solution, the patient should be closely observed for the development of hyponatremia.

To maintain an ethanol concentration of 100 mg/dL, ethanol replacement must equal ongoing elimination (66–130 mg/kg/h). The average hourly dose for a 70 kg person is 4.6 g, but higher doses are required in ethanol tolerant patients (100–154 mg/kg/h) or others who may have induced enzymes, and in those undergoing hemodialysis (250–350 mg/kg/h; Chap. 10).^{12,22,33,40,41}

ROLE IN METHANOL AND ETHYLENE GLYCOL TOXICITY

When administered in a timely fashion after the toxic alcohol ingestion and before the accumulation of the toxic metabolites, case reports confirm the efficacy of ethanol in preventing the sequelae of methanol and ethylene glycol poisoning.^{7,9,24,50,55} In the presence of sufficient inhibitory concentrations of ethanol, the half-life of ethylene glycol in two patients with normal kidney function was 17.5 hours, which was comparable with 17 hours in a case series of patients receiving fomepizole alone with normal kidney function.^{7,49} A half-life of 46.5 hours for methanol was reported in a patient who had received a sufficient blocking quantity of ethanol⁴⁰ which is quite similar to the 54 hours reported in a case series of methanol-poisoned patients treated only with fomepizole.^{5,24}

ADVERSE EFFECTS AND SAFETY ISSUES

Problems encountered with the administration of ethanol include further risk of central nervous system (CNS) depression, behavioral disturbances, or ethanol related toxicity, such as hepatitis and pancreatitis, hypoglycemia, dehydration, fluctuating serum concentrations, and potential drug interactions resulting in disulfiramlike reactions.^{3,14,18,28,34,38,39,56,59}

PREGNANCY AND LACTATION

Ethanol (injection) is US Food and Drug Administration pregnancy category C. Ethanol crosses the placenta and reaches the fetus. Ethanol is teratogenic, and the American Academy of Pediatrics (AAP) recommends that pregnant women abstain

from all alcohol consumption. It is likely that the short duration of ethanol therapy, when used to compete with alcohol dehydrogenase, during the second or third trimester, has a minimal risk of inducing fetal alcohol syndrome. Ethanol should only be used following a risk benefit analysis, particularly in the first trimester. Ethanol crosses into breast milk and may cause CNS depression and ethanol toxicity in the breast-fed infant.

DOSING AND ADMINISTRATION

Ethanol can be given either orally or IV (Tables A31–1 and A31–2). Concentrations of 20% to 30% orally and 5% to 10% IV are well tolerated. Intravenous administration has the advantages of complete absorption²⁶ and avoidance of most gastrointestinal symptoms, and can be used in an unconscious or uncooperative patient. The disadvantages of IV ethanol include difficulty in obtaining and preparing an IV ethanol solution, the hyperosmolarity of a 10% ethanol solution (~ 1900 mOsm/L), and the possibilities of osmotic dehydration, hyponatremia, and venous irritation.

TABLE A31–1. Intravenous Administration of 10% Ethanol						
Loading Dose ^a	Volume (mL) ^b (given over 1 hour as tolerated)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 10% ethanol (infused over 1 hour as tolerated)	80	120	240	400	560	800
Maintenance Dose ^c	Infusion Rate ^d (mL/h for various weights) ^e					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Ethanol naïve						
80 mg/kg/h	8	12	24	40	56	80
110 mg/kg/h	11	16	33	55	77	110
130 mg/kg/h	13	19	39	65	91	130
Ethanol tolerant						
150 mg/kg/h	—	—	—	75	105	150
During hemodialysis						
250 mg/kg/h	25	38	75	125	175	250
300 mg/kg/h	30	45	90	150	210	300
350 mg/kg/h	35	53	105	175	245	350

^aA 10% V/V concentration yields approximately 100 mg/mL. ^bFor a 5% concentration, multiply the amount by 2. ^cInfusion to be started immediately following the loading dose. Concentrations above 10% are not recommended for intravenous administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100 to 150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the infusion rate of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia. ^dRounded to the nearest mL.

TABLE A31–2. Oral Administration of 20% Ethanol

	Volume (mL)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Loading Dose^a						
0.8 g/kg of 20% ethanol, diluted in juice (may be administered orally or via nasogastric tube)	40	60	120	200	280	400
mL/h for various weights^{c,d}						
Maintenance Dose^b	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
Ethanol naïve						
80 mg/kg/h	4	6	12	20	28	40
110 mg/kg/h	6	8	17	27	39	55
130 mg/kg/h	7	10	20	33	46	66
Ethanol tolerant						
150 mg/kg/h	—	—	—	38	53	75
During hemodialysis						
250 mg/kg/h	13	19	38	63	88	125
300 mg/kg/h	15	23	46	75	105	150
350 mg/kg/h	18	26	53	88	123	175

^aA 20% V/V concentration yields approximately 200 mg/mL. ^bConcentrations above 30% (60 proof) are not recommended for oral administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100 to 150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the dose of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia. ^cRounded to the nearest mL. ^dFor a 30% concentration, multiply the amount by 0.66.

Adapted with permission from Roberts JR, Hedges J, eds. *Clinical Procedures in Emergency Medicine*. Philadelphia: WB Saunders; 1985:1073–1074.

Regardless of route, the objective is to rapidly achieve and maintain a serum ethanol concentration of at least 100 mg/dL, which is adequate for enzyme inhibition in most cases. Inhibition is best achieved by administering a loading dose of ethanol, followed by a maintenance dose.

Because ethanol elimination varies in each individual, frequent serum ethanol determinations should be obtained to ensure adequate dosing while also monitoring blood glucose and fluid and electrolyte status. In addition, any increase in the anion gap or decrease in bicarbonate concentration implies that the ethanol dose is inadequate to achieve blockade of alcohol dehydrogenase and the ethanol dosing should be increased.

FORMULATION AND ACQUISITION

A practical problem often involves preparing the ethanol to be given since commercial preparations of 5% ethanol in 5% dextrose are no longer available for IV administration.⁴ Not having a commercially available preparation increases the delay to administration of IV ethanol and the potential for a medication error in preparation. Sterile ethanol USP (absolute ethanol) can be added to 5% dextrose to make a solution of approximately 10% ethanol concentration; 55 mL of absolute ethanol is added to 500 mL of 5% dextrose to produce a total volume of 555 mL (10% = 10 mL in 100 mL; in this case, 55 mL in 555 mL or 55/555). If oral administration is chosen, then it is important to remember that in the United States the “proof” number on the label is double the concentration; that is, “100-proof” ethanol is 50% ethanol by volume (50 mL/100 mL). If there will be any delay in preparing ethanol for IV use and fomepizole is not available or used, then oral therapy with ethanol should be initiated immediately.

COMPARISON TO FOMEPIZOLE

Although ethanol has been used as an antidote for toxic alcohols for many years in both adults and children,⁴⁶ and has the advantages of easy accessibilities to oral ethanol and low acquisition cost, fomepizole is a very potent inhibitor of alcohol dehydrogenase with many important advantages.^{17,19,23,31,35,36} Fomepizole does not produce CNS depression, is easier to dose, and does not require serum concentration monitoring. Although fomepizole is more costly than ethanol, its many advantages over ethanol make fomepizole the preferable antidote (Antidotes in Depth: A30 and [Chap. 109](#)).^{28,48,56}

SUMMARY

- When administered appropriately, ethanol is an excellent first step in preventing further metabolism of methanol and ethylene glycol to their respective toxic metabolites.
- The disadvantages of ethanol compared with fomepizole (when available) make ethanol an outmoded antidote under most circumstances.
- Neither fomepizole nor ethanol affects the toxic metabolites already present in the body.
- Once alcohol dehydrogenase is blocked, the decision whether to use hemodialysis depends on the degree of end-organ damage that has occurred, how well the body can eliminate the parent compound without the benefit of hemodialysis, and the extent to which toxic metabolites are already present.
- With the use of either ethanol or fomepizole without subsequent hemodialysis, the increase in hospital length of stay in an intensive care unit or on a medical floor may be substantial for methanol poisoned patients.^{20,47}

K. PESTICIDES

CASE STUDY 9

History A 2 year-old (12 kg) girl was brought to the hospital by ambulance after having a witnessed seizure at home. The child was healthy, born at term, and without any significant past medical history. Although her family had recently immigrated to the United States, she was followed in a primary care clinic and was fully vaccinated. She had one screening test for lead, which was “normal.” Her mother relates that their house had problems with roaches, mice, and rats and she thinks her husband applied a chemical to deal with the problem.

About 20 minutes before the girl became ill, her mother saw the child pick up something from the corner of the room and immediately thereafter removed some material that looked like food from the child’s mouth. She subsequently lost consciousness and began to shake. The mother called 9-1-1 and when EMS arrived the child was intermittently seizing. Lorazepam (1 mg IM) was administered and EMS gave the child supplemental oxygen for transport. The paramedics reported that the child stopped seizing during transport but started again upon arrival to the emergency department.

Physical Examination On arrival, the child was seizing with the following vital signs: blood pressure, 90/40 mm Hg; pulse, 160 beats/min; respiratory rate, 36 breaths/min; temperature, 100°F (37.7°C); oxygen saturation, 100% on a 100% nonrebreather mask. There were no signs of trauma. The skin was moist, pupils were 4 to 5 mm and fixed, the chest was clear, heart sounds were regular, and her abdomen was soft. Neurologic examination revealed repetitive symmetrical movements of the limbs, slight eye deviation to the left, and a lack of responsiveness to stimulation.

Initial Management Another 1 mg dose of lorazepam was given IM, while an IV was being inserted. A rapid bedside glucose was 160 mg/dL, and blood samples were obtained for complete blood count, electrolytes, liver function tests, and creatine phosphokinase. The child continued to seize and a 2 mg IV dose of lorazepam was administered that terminated the seizure. Repeat vital signs were notable for a pulse of 165 beats/min and a rectal temperature of 100.6°F (38.1°C). Blood cultures were sent and the child was given an empiric dose of ceftriaxone. An ECG was obtained and showed sinus tachycardia with normal axis and intervals.

What is the Differential Diagnosis? In addition to infectious, structural, and traumatic causes for repeated seizures, the history is suggestive of pesticide poisoning. Pesticides are defined by the US Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) as “any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest, and any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant.” Since 1947, the production, use, and distribution of pesticides in the United States have been regulated under FIFRA and its subsequent amendments in 1972, 1975, and 1978. In 1970, the US Environmental Protection Agency (EPA) was given the authority to administer and enforce FIFRA regulations. Under FIFRA, all pesticides and their manufacturers must be registered with the EPA, and the pesticide must be classified for either general use or restricted use by licensed or certified applicators. Additionally, according to FIFRA, rodenticides are classified by their toxicities and must be labelled by signal words as designated in [Table CS9–1](#). The WHO applies a similar classification scheme for all pesticides based on either oral or dermal LD₅₀ as shown in [Table 113–1](#).

Table CS9–1. US Environmental Protection Agency Toxicity Classification of Pesticides

Category and Signal Word	Oral LD ₅₀ (mg/kg)	Dermal LD ₅₀ (mg/kg)	Inhalation LC ₅₀ (mg/L)	Eye Irritation	Skin Irritation
I Danger	0–50	0–200	0–0.05	Corrosive: corneal opacity not reversible within 21 days	Corrosive
II Warning	50–500	200–2000	0.05–0.5	Corneal opacity reversible within 8–21 days; irritation persisting for 7 days	Severe irritation at 72 hours
III Caution	500–5000	2000–20,000	0.5–5.0	Corneal opacity; irritation reversible within 7 days	Moderate irritation at 72 hours
IV None	> 5000	> 20,000	> 5.0	Irritation cleared within 24 hours	Mild or slight irritation at 72 hours

Unfortunately, as is so commonly the case, not only was the mother unaware of the name or type of pesticide used, but also both the original container and label were missing. Furthermore, there was a possibility that the product used was brought from the parent’s home country and was either illegal or unlicensed in the United States. As a result, clinicians are often forced to provide empirical treatment based largely on clinical diagnosis. An understanding of the likely possibilities improves both diagnostic utility and treatment decisions.

What Clinical Factors Help Narrow the Differential Diagnosis? A review of [Table CS9–2](#), and chapters throughout this text, especially those that immediately follow this case will help identify those pesticides when ingested that are most

likely to result in seizures or status epilepticus. The possible xenobiotics include organic phosphorous compounds and carbamates, organic chlorines, monofluoroacetate and fluoroacetamide, strychnine, thallium, zinc and aluminum phosphide, and tetramine. The absence of associated clinical manifestations helps eliminate some of the choices: organic phosphorous compounds and carbamates (eg, salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, miosis), thallium (the onset was rapid and there was an absence of painful peripheral neuropathy), strychnine (not true seizures, consciousness should be preserved until hyperthermia, hypoxia, or hypercarbia becomes severe), and aluminum phosphide (absence of vomiting with characteristic odor of rotten fish). Although routine laboratory testing has little utility here, the absence of a profound metabolic acidosis might suggest that monofluoroacetate and fluoroacetamide are not responsible for this clinical presentation. Certain dangerous rodenticides imported for illicit use include tetramine (status epilepticus) and aldicarb (a carbamate found in tres pasitos). Unfortunately, since there are no rapidly available tests to help establish this diagnosis, treatment will have to be based entirely on the clinical assessment.

Table CS9–2. Management of Specific Rodenticide Ingestions

Anticoagulant Name	Physical Characteristics	Toxic Mechanism	Estimated Fatal Dose	Signs and Symptoms	Onset	Antidote and/or Treatment*
Highly Toxic Signal Word: DANGER (LD₅₀ < 50 mg/kg)						
Tallinon	White, crystalline, odorless, tasteless	Interferes with mitochondrial oxidative phosphorylation	14 mg/kg	Anorexia, abdominal pain, diarrhea, gastric emptying, infection, coma, ataxia, oliguria (adult), hemolysis	12 symptoms usually after ingestion 12–14 hours delay	Activated charcoal, Proton pump inhibitors
Sodium Fluoracetate (SFA, compound 100)	White, crystalline, odorless, tasteless, water soluble	Fluoracetate is fluorinated, interferes with mitochondrial and cycle	3–7 mg/kg	Seizures, coma, tachycardia, PRTs VT, VT, ST-T wave changes, leukoencephalopathy (hypoxic/hemorrhagic)	12–20 hours	Experimental regimens (Chap. 11.5)
Sodium Fluoracetamide (compound 101)	Same as SFA	Same as SFA, fluoride toxicity	15–20 mg/kg	Same as SFA	Same as SFA	Same as SFA
Strychnine	Bitter taste	Cystine receptor antagonist on spinal cord motor neurons	Children 11 mg Adults 1–2 mg/kg	Reflexes, anxiety, sweating, hyperextension alternating with relaxation, stridor, gasp, tremor or hand grasping ("rice water"), inability to swallow, apnoeic convulsions	15–20 minutes	Good control, IV benzodiazepines, succinylcholine blockade
Toxopnepton	Heavy grey, crystalline powder, water insoluble, "rotten fish" or "phosphorus" odor, normally used as 1% concentration	Releases phosphine in contact with water or acid or in GI tract	40 mg/kg in rat	"Rotten fish" breath odor, black vomitus, GI and cardiovascular toxicity, acute respiratory distress syndrome, apnoea, coma, seizures, hepatic and renal toxicity	Within hours; inhalation may have delayed onset	Decontam with sodium bicarbonate water or milk
Trinitrophenol (yellow or white phosphorus)	Yellow, waxy paste, fat soluble, water insoluble	Local irritation and burns on contact followed by GI, liver, and kidney damage, and interferes with clotting	1 mg/kg (lower toxic if dissolved in alcohol, fat, oil)	Skin and GI burns, "smoking" brown vomit contents and stools with garlic odor, jaundice, dysrhythmias, coma, delirium, seizures, cardiac arrest	1–2 hours	Supportive care
Veronal (barbiturate)	White, crystalline powder	Interferes with oxidative phosphorylation and interferes with a variety of respiratory reactions	1–4 mg/kg	Cerebral depression and vomiting, bloody diarrhea, cardiovascular collapse, VT, toxicologic pulmonary edema, altered mental status, life-threatening gastric emptying	Barbiturates: 1 hour Death: 1–24 hours	Decontam, decontaminated with water or milk, concentration < 50 mg/L, hemodialysis to remove (barbiturate removed if acute kidney injury develops)
Veronal (barbiturate) carbonate, chloride, hydroxide	White, white, slightly bitter, long	Hypokalemia, succinylcholine blockade	25–30 mg/kg	Bradycardia, parosmia, muscle weakness, paralysis, nausea, vomiting, diarrhea, abdominal pain, prolonged QT interval, dysrhythmias, cardiac and pulmonary failure	1–4 hours	Decontam (except with Na ₂ CO ₃ or another alkali salt) (succinylcholine, potassium replacement)

PCNA (c-prothionin) V- nitrophenyl urea, base	White, eventually colored or yellow green (pink in heat, also powder)	Interacts with nucleoside metabolism in general; destroys precursors (cells, central and peripheral nervous system, and heart)	1 mg/kg	Acute and chronic, abdominal pain, severe ulceration (gastric and duodenal ulcers), hyperemia with or without leukostasis, gastric- intestinal perforation, peritonitis, necropsis	4–48 hours	Acetaminophen (paracetamol) 500 mg IV or PO (intracutaneously used, but likely unavailable), strong diuretic (furosemide)
Tetracycline (tetracycline hydrochloride, TTS, TIO)	White powder	Non-competitive GABA antagonism by direct blockade of chloride receptors	5–20 mg/kg	Intoxication with epilepsy, laryngitis, acute urinary infection	15–30 hours	Acetaminophen, antibiotics, prokinetic, muscle relaxants
Moderately Toxic Signal Word: WARNING (LD ₅₀ 50–500 mg/kg)						
α-Naphthylthiourea (ANT)	Crystals, slightly bitter, fine, fine-grained powder, white- crystalline	Acute respiratory distress syndrome	> 4 g/kg	Hypothermia, dyspnea, cardiac, acute pulmonary edema, cyanosis	1	Supportive care
Cholecalciferol (vitamin D ₃)	0.025% yellow, 0.04% white/light (1 tablet = 2000 IU vitamin D)	Hypocalcemia	1	Neutropenia, leukopenia, anemia, thrombocytopenia, acute kidney injury and failure, hypotension, hypocalcemia	Hours to days	Fluids, if severe hypocalcemia, phosphate replacement, high phosphate hemodialysis
Low Toxicity Signal Word: CAUTION (LD ₅₀ 500–5000 mg/kg)						
Red spin	White taste	Cardiovascular arrest/poisoning	1	Hypocalcemia, hypotension, renal failure, hypocalcemia	30 minutes–4 hours	Supportive care, IV, atropine
Metformin (dimethylformamide)	White crystalline, fine, powder tablets, 1% concentration	Hypoglycemia and lactic acidosis in severe cases (specific to metformin injection in oral solution form)	Unknown, toxicity at ≥ 100 mg	Hypoglycemia and hypotension	1	Supportive care
Benzocaine	7.5% concentration, green pellets, with 80% alcohol solution (benzocaine)	Hypoxia, systemic hypoxia due to rapid onset of anesthesia	1	Block nerve, muscle, joint, block of major vessels, central nervous system, local anesthetic	Immediate	Supportive care
Anticoagulants: Short Acting						
Warfarin	Yellow crystalline, white, white (0.025%)	Anticoagulation via interference with clotting factors II, VII, IX, X	> 5–20 mg/kg for ≥ 5 days	Increased PT, bleeding death from hemorrhage	12–48 hours	Warfarin, fresh frozen plasma or blood products, vitamin K, prothrombin complex concentrate
Fenitoin	Warfarin (0.025%) plus vitamin K (0.025%)	Anticoagulant activity continues for 48 hours (central nervous system) 8 weeks long exposure	10	Increased PT, bleeding death from hemorrhage		
Anticoagulants: Long Acting						
Hydrocortisone A hydrocortisone	0.025% white, white, white	Anticoagulation via interference	1	Increased PT, bleeding	Increased several days	Warfarin, fresh frozen plasma or blood

Formulation (formulation)		with chelating factor A, B, C, D	death from acute renal failure		Permethrin complex concentrate
Barbiturate (concentration)	0.1% to 0.25% white powder, tablets, tablets				
Indication:					
Propofol	White, amorphous, fully yellow powder, concentration 0.001–2.5%	Intoxication via intravenous with chelating factor A, B, C, D	Chronic ingestion possibly profound cardiac and respiratory depression, elevated BUN, bleeding, death from acute renal failure	Delayed several days	Vitamin K, fresh frozen plasma or red blood cells, Permethrin 1 complex concentrate
Propofol	0.5%				
Diazepam	0.001–2.5%				
Chlorhexidine	0.001–2.5%				
Water	0.001–2.5%				

Environmental decontamination should be provided as appropriate (Chapter 8); only unique environmental agents are discussed in this table.

The LD₅₀ values listed in this table are derived from data on acute oral ingestion of the commercial product by rats. In some cases, the commercial product contains a very small percentage of the active ingredient. The signal words that appear on labels of registered products may differ from the signal word assigned to the acute oral LD₅₀, but because the label may also reflect another study (acute dermal or inhalational LD₅₀) requiring a more severe signal word. See [Table 11.1-1](#) for the Consumer Product Safety Commission definitions and use of signal words as indicators of potential hazard of toxicity. Permethrin 1, Permethrin 1 complex concentrate, Permethrin 1 complex concentrate, EPA, Washington, DC.

Treatment Shortly after the third dose of lorazepam the child began to seize again and endotracheal intubation was performed. Following intubation the child was placed on a continuous infusion of propofol. A nasogastric tube was inserted and 10 g of activated charcoal were instilled into the stomach. The child was transferred to the PICU and attached to a video EEG monitor where intermittent seizure activity was noted over the next 12 to 16 hours. A CT scan of the head was normal and a lumbar puncture was performed to exclude meningitis. The following day the father brought in the original package and the product was identified as tetramine.

Over the subsequent 24 hours the propofol infusion was titrated to a lower dose and then discontinued. The child was able to be extubated and appeared clinically normal. Since the package was brought from their home country and not imported, authorities were not notified. The parents were educated about safe use of pesticides and a social worker was able to help coordinate legal exterminating efforts by the landlord.

Acknowledgments Authors from previous editions, including Neal E. Flomenbaum, Mary Ann Howland, Richard Weisman, Rebecca Tominack, and Susan Pond, contributed to the development of [Tables CS9–1 and CS9–2](#) as well as the discussion of FIFRA.

110 BARIUM

Andrew Dawson

Barium (Ba)		
Atomic number	=	56
Atomic weight	=	137.3 Da
Normal concentration		
Serum	<	0.2 mg/L (1.46 μ mol/L)

HISTORY AND EPIDEMIOLOGY

Although barium is utilized in various forms in developed nations, exposure to barium salts is uncommon and clinically significant poisoning is rare. Acute, clinically relevant exposures occur most commonly following the intentional ingestion of the soluble salts found in rodenticides,⁹ insecticides, or depilatories.¹⁰ Barium carbonate has an appearance similar to flour and has been responsible for most unintentional barium poisonings.^{8,12}

Barium salts and barium hydroxide are extensively employed in industry particularly in thermoplastics and the manufacture of synthetic fibers, soap manufacture, and in lubricants (Table 110–1). Toxicity occurs following occupational exposure to barium salts through ingestion, inhalation,³² or explosion of the propellant barium styphnate.¹⁴ Despite the fact that barium sulfate is insoluble, rare cases of unintentional toxicity are reported during radiographic procedures and include complications associated with oral²² and rectal administration.^{13,18,20,25} Toxicity and death occurred when soluble barium salts were unintentionally permitted to contaminate contrast solutions.²⁷

TABLE 110–1. Barium Salts: Solubility and Common Usages

Barium Salt	Solubility (mg/L at 20°C)	Common Uses
Acetate	58.8	Textile dyes
Carbonate	0.02 increases in an acid pH; also, can be converted to barium chloride by gastric acid (HCl)	Rodenticide, welding fluxes, pigments, glass, ceramics, pyrotechnics, electronic devices, welding rods, ferrite magnet materials, optical glass, manufacture of caustic soda and other barium salts
Chloride	375	Textile dyes, pigments, boiler detergents, in purifying sugar, as mordant in dyeing and printing textiles, as water softener, in manufacture of caustic soda and chlorine, polymers, stabilizers
Fluoride	1.2	Welding fluxes
Nitrate	87	Optical glass, ceramic glazes, fireworks (green), explosives, antiseptic preparation
Oxide	34.8	In glass, ceramics, refining oils and sugar, as an additive in petroleum products and also as materials of plastics, pharmaceuticals, polymers, glass and enamel industries
Styphenate	—	Propellant used in manufacture of explosive detonators
Sulfate	0.002	Radiopaque contrast media, manufacture of white pigments, paper making
Sulfide	Slightly soluble in H ₂ O	Depilatories, manufacture of fluorescent tubes

CHEMISTRY

Barium is a soft metallic element that was first isolated by Sir Humphry Davey in 1808. With an atomic weight of 137.3 Da, barium is located at number 56 in the periodic table (between cesium and lanthanum). The metal oxidizes easily when exposed to water or alcohol, has a melting point of 1341°F (727°C) and a boiling point of 3398°F (1870°C). Elemental barium is not found in nature; it normally occurs as an oxide, dioxide, sulfate (barite), or carbonate (witherite). Chemically,

barium resembles calcium more than it resembles any other element. While some barium salts are naturally occurring, most used commercially are produced from the more commonly found carbonates or oxides. Barium salts are typically classified as either water soluble or insoluble, but the solubility of all barium salts increases as the milieu becomes more acidic. The soluble salts acetate, chloride, hydroxide, oxide, nitrate, and (poly) sulfide are the most commonly associated with toxicity (Table 110–1). Barium (poly) sulfide also produces toxicity through the formation of hydrogen sulfide when ingested and exposed to gastric hydrochloric acid.

The solubility of barium carbonate is low at physiological pH, but it increases significantly as the pH is lowered. In the presence of gastric acid conversion to the highly soluble barium chloride occurs. The other insoluble barium salts such as arsenate, chromate, fluoride, oxalate, and sulfate are rarely associated with toxicity. However, toxicity has occurred in the unusual situation of intravasation of barium sulfate (see Toxicokinetics).

TOXICOKINETICS

Toxicity can result from ingestion of as little as 200 mg of a barium salt. Oral lethal doses are reported to range from 1 to 30 g of a barium salt. Occupational exposure to barium fumes of greater than 0.02 mg/m³ are associated with health effects.³⁶ Exposure to inhaled particulate barium may cause pulmonary baritosis, which consists of very fine punctate and annular lesions and some slightly larger nodular lesions.³⁶

Following ingestion, 5% to 10% of soluble barium carbonate salts are absorbed,¹⁵ with the rate of absorption dependent on the degree of water solubility of the salt. The time to peak serum concentration is 2 hours.¹⁵

The toxicokinetics are characterized by a rapid redistribution phase, followed by a slow decrease of serum barium concentrations, with a reported half-life ranging between 18 and 85 hours.^{15,26} Renal elimination of the absorbed dose accounts for 10% to 28% of total barium excretion, with the predominant route of elimination through the gastrointestinal tract in the feces.

Serum barium concentrations range from 3.7 to 41.1 mg/L in published case reports of symptomatic patients.^{2,8,21,23,26,29,31} Death is uncommon following exposure but occurs most commonly following ingestion in clinical settings with limited health care resources.¹² Death from an ingestion of barium chloride was associated with the following barium concentrations at autopsy: blood, 9.9 mg/L; bile, 8.8 mg/L; urine, 6.3 mg/L; and gastric contents, 10 g/L.¹⁶

Intravasation is a rare but serious complication of radiologic studies in which barium sulfate is administered under pressure, such as a barium enema. Following a small perforation, barium sulfate leaks into the peritoneal cavity or portal venous system.²⁰ Although sudden cardiovascular collapse may occur, it is unclear whether this is the result of venous occlusion (pulmonary embolism), overwhelming sepsis, or barium toxicity.^{6,30,35} In at least one case report of intravasation, signs and symptoms were consistent with barium toxicity and elevated barium concentrations were confirmed.²² If hypokalemia is present, then barium toxicity should be assumed.

Additionally, intravenous administration of barium sulfate has occurred as the result of iatrogenic error. Rapid recognition followed by aspiration through a central venous catheter was associated with a good outcome.²⁸

PATHOPHYSIOLOGY

At a cellular level barium induces hypokalemia by two synergistic mechanisms. Barium is a competitive blocker of calcium activated potassium efflux channels. It may also directly increase cell membrane permeability to sodium. This causes a secondary increase Na⁺-K⁺ pump electrogenesis leading to a shift of extracellular potassium into the cell.

Intracellular trapping of potassium leads to depolarization and paralysis.¹⁷ Additionally, the inhibition of potassium channels increases vascular resistance and reduces blood flow^{3,5} and is the likely mechanism for hypertension and metabolic acidosis with an elevated lactate concentration.

While severe hypokalemia contributes significantly to paralysis, some authors have found that muscle weakness correlates better with barium concentrations than with potassium concentrations.^{23,31} This suggests a possible direct effect of barium on either skeletal muscle or neuromuscular transmission.

CLINICAL MANIFESTATIONS

Abdominal pain, nausea, vomiting, and diarrhea commonly occur within 2 hours of ingestion.¹² Esophageal injury and hemorrhagic gastritis are also reported.^{1,16}

Severe hypokalemia is the cardinal feature of barium toxicity and can occur within 2 hours following oral or parenteral exposure. Hypokalemia may be exacerbated by blood transfusions, suggesting that fresh red blood cells provide a new reservoir for K⁺ sequestration.¹⁴ Progressive hypokalemia is associated with severe ventricular dysrhythmias, hypotension,

profound flaccid muscle weakness, and respiratory failure (Chaps. 16, 16, and 3).

Other effects less commonly reported include metabolic acidosis with an elevated lactate concentration, hypophosphatemia, and rhabdomyolysis.¹⁵ Altered level of consciousness, seizures,⁷ and parkinsonism with findings on magnetic resonance imaging of bilateral hyperintensity of the basal ganglia are reported.¹¹ It is unclear whether these later findings are due to direct toxicity, deposition of barium, or secondary to tissue ischemia.

DIAGNOSTIC TESTING

Barium can be measured by a variety of techniques. Mass spectrometry and graphite furnace atomic absorption spectrometry can quantitate barium in blood and urine.¹⁷ Serum barium concentrations are not readily available, but values greater than 0.2 mg/L are considered abnormal.⁴

Following acute exposures, patients should have serum electrolytes (particularly potassium and phosphate) measured hourly while performing continuous electrocardiographic monitoring. Creatine phosphokinase (CPK), acid base status, and kidney function should also be measured. Plain abdominal radiography may show barium, but the sensitivity and specificity of radiography has never been determined for barium poisoning.¹⁷

MANAGEMENT

Toxicologic etiologies for flaccid paralysis such as hypermagnesemia, botulism, and the administration of neuromuscular blockers should also be considered while the serum potassium concentration is being evaluated. Once the hypokalemia is diagnosed, other causes of acute hypokalemia (Chap. 19) associated with paralysis such as periodic hypokalemic paralysis, toluene toxicity, and diuretic use should be considered if there is no history or laboratory confirmation of barium exposure.

Patients who are asymptomatic at 6 hours following ingestion with normal potassium concentrations can be discharged. Patients with signs or symptoms of toxicity should be admitted to an intensive care unit with expectant management of respiratory compromise and cardiovascular instability.

DECONTAMINATION

Activated charcoal is unlikely to be effective. Orogastric lavage should be considered in patients who present early after ingestion, but lavage is unlikely to provide substantial benefit in patients who are already symptomatic or who have had spontaneous emesis. Oral sodium sulfate administration may prevent absorption by precipitating unabsorbed barium ions as insoluble, nontoxic barium sulfate. Oral magnesium sulfate has had similar efficacy.¹⁹ The oral dose of magnesium sulfate is 250 mg/kg for children and 30 g for adults. Intravenous magnesium sulfate or sodium sulfate is not advised as it may lead to acute kidney injury due to precipitation of barium in the renal tubules.^{23,34}

Patients in respiratory failure should receive assisted ventilation. Expedient correction of hypokalemia is important to minimize the risk or to treat cardiac dysrhythmias. Large doses of potassium replacement (400 mEq in 24 hours) may be required to correct serum potassium although repletion may be inadequate to improve the resting membrane potential or muscle strength¹⁷ (Chap. 19). As hypokalemia is due to intracellular sequestration of potassium, potassium supplementation increases the total body potassium load. In this situation, rebound hyperkalemia may occur when barium is eliminated, especially in patients with acute or chronic kidney disease. Observation and serial evaluation for this clinical complication is essential.

Elimination Enhancement

If hypokalemia is unable to be corrected or if the correction of hypokalemia does not restore normal motor function and muscle strength, hemodialysis should be considered. Case reports suggest that hemodialysis for the management of severe barium toxicity is associated with rapid clinical improvement.^{2,26,29,33} Additionally, in a case report, continuous veno-veno hemodiafiltration provided a clinically significant increase in measured barium elimination, stabilized serum potassium concentrations, and was associated with rapidly improved motor strength.¹⁷ Either method of enhanced elimination should be considered in any severely symptomatic patient who does not respond to correction of hypokalemia.

Management of Intravasation

Following intravasation of oral barium sulfate patients should be admitted to an intensive care unit. Expectant management should include considerations of intraabdominal sepsis, hemorrhage and trauma, pulmonary embolus, and barium toxicity.²⁰ Prophylactic antibiotics seem reasonable and serial determinations of serum potassium concentrations are warranted. Computed tomography scanning of the chest and abdomen can demonstrate both the location and extent of the barium sulfate

administered.³⁰

SUMMARY

- Although poisoning by barium salts is rare, these salts are widely used in industry and therefore represent a substantial risk for human exposure.
- The hallmark of barium salt toxicity is rapidly developing and severe hypokalemia with attendant weakness progressing to paralysis.
- In addition to supportive care the mainstay of treatment is rapid correction of hypokalemia.
- Hypokalemia results from an intracellular shift of potassium. As toxicity resolves and potassium redistributes into the extracellular space, cautious evaluation for the development of hyperkalemia is essential.
- Extracorporeal therapies should be considered in cases of refractory hypokalemia.

111 FUMIGANTS

Shahin Shadnia

Proper use of pesticides can have a beneficial role in human health by increasing the quality and quantity of crops. Alternatively, their improper use can lead to a variety of acute and chronic poisonings.⁵⁶ Pesticide poisoning is a global public health problem,⁵⁴ and each year approximately 300,000 deaths occur worldwide due to pesticides.⁵³

Fumigants are nonspecific pesticides applied to kill and control rodents, nematodes, insects, weed seeds, and fungi anywhere in soil, on structures, crops, grains, and commodities.⁴⁹ They represent a diverse group of xenobiotics that are dissimilar in their chemical structures, physical properties, and mechanisms of toxicity (Tables 111–1 and 111–2). Many fumigants, particularly the halogenated solvents, have been largely abandoned because of their toxicity. In the 1987 Montreal Protocol, an international agreement was adapted to phase out ozone-depleting chemicals, such as methyl bromide, which was scheduled to be discontinued in 2005. Unfortunately, many agricultural companies received exemptions, as satisfactory substitutes for some of its uses have not emerged.

TABLE 111–1. Physical Properties and Industrial Uses of Fumigants

	<i>Color</i>	<i>State</i>	<i>Flammability</i>	<i>Odor</i>	<i>Use</i>
Phosphine	Colorless	Gas	High	Rotten fish Garlic	Rodenticide
Methyl bromide	Colorless	Gas	No	None ^a	Soil Structural Crop
Dichloropropene	Yellow	Liquid	No	Garlic	Soil
Sulfuryl fluoride	Colorless	Gas	No	None	Structural

^aIt has a sweet chloroformlike smell at high concentrations.

– = Absence; + = Presence; ++ = Very substantial; ± = Variable.

Since fumigants exist as solids that can release toxic gases on reacting with water (zinc phosphide, aluminum phosphide) or with acids (sodium or calcium cyanide), as liquids (ethylene dibromide, dibromochloropropane, formaldehyde) that can vaporize at ambient temperature, or as gases (methyl bromide, hydrogen cyanide, ethylene oxide),

inhalation is the most common route of exposure (Table 111–1). In their gaseous forms fumigants are generally heavier than air and will stay concentrated just above the ground surface and lower floors of buildings.

Their exposure risk is enhanced by their general lack of good warning properties, non–species-selective effects, and high potency. Although chemicals from many different classes were used in the past as fumigants, only a few remain in use today in the United States. This chapter summarizes those remaining and also highlights important fumigants that are in use in developing countries.

PHOSPHIDES AND PHOSPHINE

Introduction

In addition to the organic phosphorus and organic chlorine compounds, metal phosphides (aluminum, zinc, magnesium, and calcium) have long been used as rodenticides and fumigants around the world. The metal phosphides are advantageous due to their low cost, high effectiveness in destroying harmful insects and rodents, freedom from toxic residue, and lack of adverse effect on seed viability. Phosphides are used to protect grain held in silos, in the holds of ships, and during transportation by rail. They are generally admixed with the grain at a predetermined rate at the initiation of storage.^{26,56} Upon exposure to ambient moisture, the metal phosphides release phosphine gas (PH₃). Exposure to water results in rapid release highlighting the concern for their use as chemical weapons.¹⁶

History and Epidemiology

From 1900 until 1958 only 59 cases of PH₃ and metal phosphides poisoning were reported in the literature, the majority of which were unintentional. Fatal outcomes were reported in 26 of these cases.^{95,105} Over the last 35 years, cases of poisoning have escalated, carrying a high mortality rate, likely related to the use of these chemicals for suicidal purposes.¹²⁰ Aluminum phosphide (AIP) poisoning is now one of the commonest causes of poisoning in agricultural societies, such as those found in India, Sri Lanka, Iran, Jordan, and Morocco.^{16,46,48,96,115,120} The incidence of phosphide poisoning is rare in Europe and North America.^{100,107}

Physicochemical Properties

Commercially, AIP is most widely available as a greenish-gray tablet that has a garlic odor. The tablets usually contain 3 g of AIP (56%), ammonium carbamate, and urea. Zinc phosphide (Zn₃P₂; molecular weight of 258.1 Da) is available as a dark gray powder and or quadrilateral crystals that has odor of acetylene or rotten fish. Calcium phosphide (Ca₃P₂; molecular weight of 182.2 Da) is available as a reddish-brown crystal powder.⁹

In the presence of moisture, phosphide is converted to gaseous PH₃ (hydrogen phosphide, phosphorus trihydride), ammonia, and carbon dioxide:

OR

Each AIP tablet liberates up to 1 g of PH₃. The release of PH₃ is even more vigorous after contact with an aqueous acid, such as hydrochloric acid. The residue Al(OH)₃ is nontoxic.^{9,48,136} PH₃ may be flammable, and other byproducts of commercial tablets (aluminum oxide and diphosphine gas) are spontaneously flammable in air.^{38,69,117,146,147}

Although PH₃ is colorless and odorless in pure form up to toxic concentrations (200 parts per million {ppm}), the presence of substituted phosphines and diphosphines imparts a decaying fish or garlic odor that is detectable at concentrations of as little as 2 ppm.^{26,27,104}

Toxicokinetics

Following ingestion, the most common route of exposure, metal phosphides react with acidic fluid in the gastrointestinal (GI) tract to release PH₃, which is rapidly absorbed. Phosphides may be absorbed as microscopic particles of unhydrolyzed salt and subsequently converted to PH₃. PH₃ can be absorbed from respiratory tract mucosa if inhaled. Dermal and ocular absorption occurs.⁹

There are no data on the distribution of PH₃ to tissues, but one would expect this small soluble molecule to readily

reach all organs.^{9,89} PH₃ is detectable in the blood and liver of decedents following ingestion.^{6,32} Hypophosphite is the major degradation product in the urine, and smaller amounts of phosphate and phosphite may be identified, while PH₃ itself is exhaled.⁵⁷

Toxicodynamics

PH₃ is a protoplasmic toxin that interferes with enzymatic function and synthesis of proteins.¹²⁰ The mechanism of toxicity includes blocking the electron transport chain and oxidative phosphorylation through noncompetitive inhibition of cytochrome-c oxidase. This inhibits cellular respiration and leads to the formation of highly reactive hydroxyl radicals that cause additional damage.^{17,42,123} PH₃ also inhibits catalase, induces superoxide dismutase, and reduces the glutathione (GSH) concentration. All of these effects combine to result in lipid peroxidation and protein denaturation of cell membranes, leading to widespread cellular damage and ion channel dysfunction.^{30,31,34,65}

PH₃ directly injures the alveolar capillary membrane in addition to producing oxidative injury, leading to acute respiratory distress syndrome (ARDS).^{57,120} Although both AIP and PH₃ inhibit cholinesterase activity, this effect is unlikely to have substantial clinical relevance.^{3,84,85,94,108}

Toxic Dose

Ingestion of 1 g of ZnP can cause toxicity in humans and death has been reported after ingestion of 4 g. Ingestion of 500 mg of AIP can be fatal.¹⁰ The recommended exposure limit (REL) of PH₃ in workplace is less than 0.3 ppm as a time-weighted average (TWA) for up to 10 hours per day during a 40 hour work week, and 1 ppm as a 15-minute short-term exposure limit (STEL) that should not be exceeded at any time during a workday. The National Institute of Occupational Safety and Health has established 50 ppm as the concentration that is immediately dangerous to life or health (IDLH) for PH₃, and the concentration of 400 to 600 ppm could be lethal within 0.5 hours.^{98,132} Workplace standards are not available for AIP specifically.¹³²

Clinical Manifestations

The smell of garlic or decaying fish on the breath is a common finding and can be the result of oral or inhalational poisoning with phosphides and PH₃.¹⁰⁷ The clinical manifestations are dependent on the dose, route of entry, and time since exposure.⁵⁷ After ingestion, the onset of toxicity usually is slightly more rapid for AIP (10–15 minutes) than for ZnP (20–40 minutes).^{56,74} In patients with mild poisoning, nausea, repeated vomiting, diarrhea, abdominal discomfort or pain, especially epigastric pain, and tachycardia are common clinical manifestations. In those with moderate to severe effects, GI manifestations, refractory hypotension and shock, palpitations, cardiovascular collapse, dysrhythmias, tachypnea, and ARDS occur early.^{48,109}

Restlessness, anxiety, dizziness, ataxia, numbness, paresthesias, and tremor are universally observed, but central nervous system (CNS) manifestations are not prominent until a secondary event, such as hypoxia occurs. Late and severe neurologic findings include delirium, convulsions, and coma.

Following limited PH₃ inhalational exposure, patients commonly have airway irritation and breathlessness.²⁶ Other features may include dizziness, tightness in the chest, headache, nausea, vomiting, diarrhea, ataxia, numbness, paresthesias, tremor, muscle weakness, and diplopia.^{48,56,132} In patients with significant inhalations, ARDS, cardiac failure, dysrhythmias, convulsions, coma, and delayed manifestations of hepatotoxicity and nephrotoxicity may also occur.^{48,132}

Uncommon complications of phosphides and PH₃ poisoning include gastroduodenitis, hepatitis,³⁵ ascites,¹⁴ pancreatitis,¹⁴³ myocardial infarction,^{72,76} acute pericarditis,²⁷ pleural effusion,¹³³ skeletal muscle damage and rhabdomyolysis,¹⁰⁹ acute tubular necrosis, adrenocortical congestion, hemorrhage and/or necrosis,⁷ and delayed esophageal stricture or tracheoesophageal fistula.^{73,81,142} Hepatic and kidney failure, as well as disseminated intravascular coagulation (DIC), may occur following acute poisoning.^{14,48,109}

Diagnostic Testing

Initial investigations should include electrocardiography (ECG) and continuous cardiac monitoring, chest radiograph, blood glucose, blood gases, serum electrolytes, complete blood count, and liver and kidney function studies. Hypokalemia is common after oral poisoning and is probably due to vomiting, although this effect may be catecholamine related.¹⁰⁹ Magnesium concentrations may be normal,¹²⁴ increased, or decreased.^{23,25,28,29,121,122}

Hypoglycemia as a result of impaired gluconeogenesis, glycogenolysis, and possibly due to adrenal insufficiency is

common and may be severe and persistent.^{36,45} Hyperglycemia has also been reported.^{89,90} Metabolic acidosis or mixed metabolic acidosis and respiratory alkalosis are common.¹⁰⁹ Intravascular hemolysis, methemoglobinemia, and microangiopathic hemolysis are unusual complications of phosphide poisoning.^{77,118,127}

ECG abnormalities are very common, but highly variable, and include rhythm disturbances, ST segment and T wave changes, and conduction defects.^{25,71,128} During the first 3 to 6 hours after poisoning, sinus tachycardia is predominant, followed over the next 6 to 12 hours by ST segment and T wave changes, conduction disturbances, and dysrhythmias.^{45,126} Ventricular tachycardia, ventricular fibrillation, supraventricular tachycardia, and atrial flutter/fibrillation are the most common consequential dysrhythmias.¹²⁵ Echocardiography may reveal dysfunction, dilation, and hypokinesia or akinesia of the left ventricle that typically resolves over several days.^{2,15,55}

Toxicological Analyses. Chemical analysis for PH₃ in blood or urine is not recommended and is not typically helpful as PH₃ is rapidly oxidized to phosphite and hypophosphite.¹⁴⁷ Gas chromatography with a nitrogen-phosphorous detector is the most specific and sensitive test.⁹⁷ The presence of PH₃ is suggested by a positive silver nitrate test on gastric content or exhaled breath. In this test which is not clinically available and is not validated paper impregnated with silver nitrate will turn black (silver phosphate) in the presence of PH₃.⁹³

Prognosis

The mortality rate following metal phosphide ingestion is 31% to 77%.^{23–25,116} Most of the deaths occur within 12 to 24 hours and are due to cardiovascular collapse.^{5,128} After 24 hours, most of the deaths are due to refractory shock, severe acidemia, and ARDS.¹⁴⁵ Fulminant hepatic failure may develop within 72 hours after poisoning and may be another cause of death.⁷

A high Acute Physiology and Chronic Health Evaluation Score, a high Simplified Acute Physiology Score, shock, decreased level of consciousness, lack of vomiting after ingestion, acidemia, hyperglycemia, uremia, hemoconcentration, leukocytosis, and ECG abnormalities are all poor prognostic factors.^{23–25,80,89,90,115,116,128}

Treatment

The victim of PH inhalation should immediately be removed to fresh air and supplemental oxygen should be provided as needed.^{57,109} Clinical staff and other health care professionals should use universal precautions, including gloves and masks,⁹³ with the understanding that a particulate mask will not protect against PH₃. As PH₃ may be absorbed by the cutaneous route, the patient's clothes should be removed and their skin and eyes decontaminated with water as early as possible.⁴⁸ GI decontamination may be useful if it is done within 1 to 2 hours of ingestion. The acidic content of stomach assists the conversion of phosphide to PH₃, and some have suggested the oral administration of sodium bicarbonate, but this is not supported by experimental evidence.^{57,82} Potassium permanganate (1:10,000) has also been suggested in case reports as an adjunct to gastric lavage to oxidize PH₃ to nontoxic phosphate.^{82,103}

There is limited evidence that activated charcoal (AC) 100 g may reduce GI absorption if the patient arrives within 1 hour after ingestion of a large amount of poison. Its routine use is not recommended as PH₃ is rapidly absorbed from the GI tract.⁸² In vitro studies suggest that lipid, mainly vegetable oils and liquid paraffin, inhibit PH₃ release from the ingested ALP.⁵¹ This approach was utilized in a single case report.¹¹⁴

Management should be rapidly initiated based on a history and clinical examination that support phosphides/PH₃ poisoning, and should not be delayed for the confirmatory diagnosis.⁵⁷ Standard supportive care to address ventilatory and vital sign abnormalities should be administered. If necessary, norepinephrine or phenylephrine should be employed. Vasopressors with greater β -receptor agonist action like dopamine and dobutamine should be used cautiously as they are prone to induce dysrhythmias.⁵⁷

As there is no known specific antidote, management remains primarily intensive monitoring and supportive treatment, to allow the toxin to be eliminated. ARDS, hypoglycemia, hypokalemia, and metabolic acidosis should be managed conventionally.^{57,109}

Dysrhythmias should be treated with standard antidysrhythmics. Recently, a few studies hypothesized that treatment with digoxin could have beneficial effects on myocardial contractility and blood pressure.^{91,112}

The benefit of hyperinsulinemia-euglycemia treatment is suggested by preliminary investigations in that insulin promotes energy production from carbohydrates, restores calcium flux, and improves myocardial contractility.⁵⁹ The use of an intraaortic balloon pump is reported,¹¹⁹ but the usefulness of extracorporeal life support in circulatory failure due to phosphides/PH₃ poisoning was not formally evaluated.¹³

N-acetylcysteine (NAC) has been shown in an experimental animal model⁸ and human study¹³⁵ to be beneficial. As the experimental and clinical evidence shows that both PH₃ and aluminum inhibit acetylcholinesterase,^{3,84,85,108} pralidoxime may have a role in the management. Further studies are recommended to confirm usefulness of oximes,⁹⁴ and they are not currently recommended.

Experimental data show that hyperbaric oxygenation may improve the survival time of poisoned rats, with no change in the mortality rate.¹¹¹ Magnesium sulfate acts as a cell membrane stabilization factor and, possibly by this mechanism, reduces the incidence of fatal dysrhythmias.^{28,29} Magnesium also has antioxidant effects and combats free radicals due to PH₃.^{33,34} Although likely of low risk, the use of magnesium sulfate in phosphides/PH₃ poisoning is controversial.^{57,109} Hemodialysis is not very effective in removing PH₃, although it may be useful in the setting of a patient with acute kidney failure, severe metabolic acidosis, or fluid overload.⁵⁷ As stated previously, the sole recognized approach remains intensive care monitoring and supportive treatment. All other approaches remain experimental.

METHYL BROMIDE

History and Epidemiology

Methyl bromide was used as an anesthetic in the early 1900s, but fatalities halted this practice. Today, methyl bromide is used widely as a fumigant for all types of dry food stuffs, in grain elevators, mills, ships, warehouses, greenhouses and food-processing facilities for the control of nematodes, fungi and weeds. It is termed a structural or commodity fumigant which is a class term for the Environmental Protection Agency.

Methyl bromide is also used as a methylating chemical in manufacturing and as a low-boiling solvent for extracting oils from nuts, seeds and flowers. Methyl bromide has also been used as a refrigerant and fire retardant. Historically, poisoning incidents involving the general public were mainly associated with the methyl bromide used in fire extinguishers. Other poisoning incidents have involved unauthorized entry into buildings being fumigated with methyl bromide.^{12,60}

Occupational and environmental exposures to methyl bromide as a fumigant are most common. Hazardous materials incidents are reported for methyl bromide, during manufacture or as a result of use and transport,^{20,106} but they are relatively uncommon in plant employees or residents living adjacent to agricultural fields where methyl bromide is applied.²⁰ Before 1955, the majority of methyl bromide poisonings resulted from chemical manufacture and filling operations. Since then, fumigation has become the major source of fatalities and fumigators, and greenhouse workers are the highest risk group. In many countries the use of methyl bromide is restricted to trained and licensed personnel.⁴⁴

Methyl bromide has a threshold limit value-time weighted average (TLV-TWA) of 5 ppm and IDLH concentration is 2000 ppm. The Occupational Safety and Health Administration (OSHA) permissible exposure limit is 20 ppm.

Methyl bromide is a colorless gas at room temperature and standard pressure. It is three times heavier than air. It is odorless except at high concentrations when it has a burning taste and a sweet chloroformlike smell. Commercially it is available as a liquefied gas. The formulations also may contain chloropicrin or amyl acetate as a warning agent.

Toxicokinetics

Inhalation is the primary route of exposure, although methyl bromide is rapidly absorbed through the dermal and oral routes. After absorption, methyl bromide or metabolites are rapidly distributed to many tissues, including the lungs, adrenals, kidneys, liver, brain, testis, and fat. The major organs of distribution observed immediately after exposure includes fat, lungs, liver, adrenals, and kidneys.

The metabolism of methyl bromide has not been completely elucidated. Methyl bromide is partially converted to inorganic bromide in man and bromide concentrations in blood and target organs increase after exposure to methyl bromide.^{12,64} It is metabolized to methyl glutathione by the enzyme glutathione S-transferase (GST) and is then converted into the neurotoxic metabolites of methanethiol and formaldehyde.⁷⁹

Depending on the route of exposure, 16% to 40% is eliminated as metabolized methyl bromide in the urine and only 4% to 20% is eliminated in the expired air as parent compound. Biliary excretion accounts for about 46% of the elimination, generally within 24 hours following oral exposure.^{4,87,88} Methyl bromide is hydrolyzed and produces methanol and hydrobromic acid in animal models.

Toxicodynamics

The mode of action of methyl bromide is still not understood. Several mechanisms of toxicity are postulated, including the direct cytotoxic effect of the intact methyl bromide molecule or toxicity due to one of its metabolites.

Methyl bromide is a potent alkylating agent with high affinity for sulfhydryl and amino groups. It reacts in vitro with a number of sulfhydryl-containing enzymes and causes irreversible inhibition of microsomal metabolism.^{12,50,129}

It binds to amine groups in amino acids, interfering with protein synthesis and function. Also it may methylate many other cellular components such as GSH, proteins, DNA, and RNA.¹³⁰ The methanethiol and formaldehyde metabolites may have a role in neurologic and visual changes. The bromide ion concentrations are insufficient to explain methyl bromide toxicity.

Clinical Manifestations

Inhalation of more than 10,000 ppm for more than a few minutes may cause death.⁶⁰ Severe poisoning may result in tremor, convulsion, rapid loss of consciousness, dysrhythmias, and death. Convulsions generally occur in fatal cases, but ARDS leading to respiratory failure or cardiovascular collapse is the leading cause of death. Pulmonary symptoms begin with cough or shortness of breath that may rapidly progress to bronchitis, pneumonitis, and ARDS.⁶³ By contrast, following low concentration exposure, a characteristic delay of up to 48 hours in the onset of symptoms is expected. Headache, dizziness, abdominal pain, nausea, vomiting, chest pain, and difficulty breathing are the manifestations of mild to moderate exposure. Some individuals may initially manifest irritant symptoms of the eye, nasopharynx, and oropharynx, which may be misdiagnosed as influenza or another viral illness. Visual disturbances such as blurred or double vision may also appear.^{22,49}

The neurologic effects of methyl bromide poisoning are the most consequential and may occur without antecedent irritant effects. Initial CNS signs and symptoms that may manifest in the first few hours after exposure include headache, dizziness, numbness, drowsiness, euphoria, confusion, diplopia, dysmetria, dysarthria, agitation and mood disorders, or inappropriate affect. Those that may progress rapidly in the first day or manifest over the next few days include ataxia, intention tremor, fasciculation, myoclonus, delirium, seizures, and coma.^{39,40}

Methyl bromide can also cause skin lesions, including severe irritation, erythema, corrosive skin injury, blisters, and vesicles predominantly in moist areas or pressure points such as groin, axilla and wrist.¹⁴⁸ Liver and kidney damage have also been described.^{12,60}

Most patients who develop seizures or coma will not survive, and in the few survivors recovery typically may take months. Permanent sequelae such as neuropsychiatric impairment, ataxia, muscular weakness, irritability, blurred vision, myoclonus, and electroencephalographic (EEG) disturbances are frequent.^{19,137}

Diagnostic Testing

The standard laboratory evaluations such as a complete blood count, serum electrolytes, blood urea nitrogen (BUN) creatinine, ammonia concentration, blood gases, urinalysis, hepatic enzymes, chest radiography, ECG, and EEG should be obtained after an acute exposure. Hemoglobin adducts are used as a biologic index for exposure to methyl bromide.⁷⁰ Hemoglobin adducts have a life span of about 2 months, so workers who have only intermittent exposure to methyl bromide may benefit from testing.

Although a serum bromide concentration may help confirm the diagnosis, it is not readily available in most laboratories. Furthermore, it does not always correlate with the severity of the exposure and does not facilitate clinical management. Serum bromide concentrations may also remain elevated for a week or more following an acute exposure.⁶⁶

The findings on magnetic resonance imaging following methyl bromide intoxication are symmetric T2 signal abnormalities in posterior putamen, subthalamic nuclei, restiform bodies, vestibular nuclei, inferior colliculi, and periaqueductal gray matter and also symmetric involvement of inferior colliculi and periaqueductal gray, as well as dentate nuclei, dorsal pons, and inferior olives.⁴⁷

Treatment

Rescue and decontamination should be performed only by personnel wearing personal protective equipment. In patients with respiratory and cardiac arrest, cardiopulmonary resuscitation should be initiated immediately if it is safe to perform. Following inhalation, the patient should be safely removed from the exposure site. The outer clothing should be removed carefully, as methyl bromide may adhere to clothing, including rubber and leather, and the affected skin should be washed with soap and water. Decontamination includes irrigation of the eyes with copious amounts of 0.9% NaCl solution or water. It is also reasonable to administer at least one dose of oral AC following ingestion, although there is no supporting documentation for any benefit. Medical management should proceed as it would for any hazardous materials event ([Chap. 131](#)).

Management is primarily general and supportive care, and may require intensive care unit management of coma, seizures, ARDS, hepatic and kidney failure. Administer supplemental oxygen and treat bronchospasm, ARDS, and seizures. Seizures are common and difficult to control with traditional anticonvulsants such as benzodiazepines and phenytoin. Pentobarbital, high-dose thiopental, and propofol have been required in many cases.⁶⁶ All exposed patients should be monitored for a minimum of 24 to 48 hours to detect delayed symptoms, especially ARDS.

Although British anti-Lewisite (dimercaprol) has been used for the treatment of methyl bromide poisoning, its effectiveness is only reported in less severely affected patients.⁶⁰ The usage of NAC is not studied in controlled prospective trials, but its effectiveness is reported in mild to moderate poisonings.⁶⁶

There are no data indicating the benefit of alkalinization or hemoperfusion. Hemodialysis can rapidly clear serum bromide, but tissue injury following exposure occurs as the bromide is released into the serum, suggesting that the methylation of neuronal proteins has already occurred and the neurologic injury occurs. Posthemodialysis neurologic improvement is reported, but severe disabilities may remain. There is little evidence to support routine hemodialysis. There is little evidence to support these experimental approaches.

DICHLOROPROPENE

History and Epidemiology

1,3-Dichloropropene is a volatile chlorinated aliphatic hydrocarbon that was introduced in 1945 and is primarily used as a soil fumigant for nematodes. Its use escalated after the restriction of ethylene dibromide, methyl bromide, and dibromochloropropane in 1956. The current formulation contains dichloropropene in soybean oil.¹³⁸

Exposures are reported during production, application, and ingestion, most commonly in occupational settings where formulations are manufactured or applied. Unintentional releases during transport resulted in several poisonings.⁸³ The OSHA standard TLV-TWA for dermal exposure is 1 ppm.⁷⁸

Toxicokinetics

Dichloropropene is rapidly absorbed by the oral, inhalational, and dermal routes. Oral exposure is theoretically possible through contaminated groundwater, but this has not been reported in humans.¹³² Inhalation is the primary route of human exposure and dichloropropene is rapidly absorbed from the lungs.^{18,140}

No human data describe systemic distribution, but animal studies show that tissue concentrations after dichloropropene ingestion were highest in the stomach, followed by the blood, bone, brain, heart, kidneys, liver, bladder, skin, skeletal muscle, spleen, ovaries, testes, and fat.⁴¹

The metabolism of dichloropropene is similar to that of other chlorinated hydrocarbon solvents such as carbon tetrachloride and chloroform (Chap. 108). In humans, dichloropropene is metabolized in liver via oxidation in a phase I biotransformation,^{86,92,131} which is catalyzed by cytochrome P450 (CYP2E1)⁵² and then glutathione dependent biotransformation.^{18,102,140,141} Toxicity may result from metabolism via an electrophilic epoxide intermediate.¹⁴⁴

Most of the glutathione-conjugated form of dichloropropene is eliminated by the kidneys and smaller amounts are eliminated in the feces.^{37,67,138}

Toxicodynamics

Human and animal health effects may include damage to the liver, kidney, lung, CNS, myocardium, GI tract, skin, and mucous membranes. The exact mechanisms of toxicity are not clear, but data suggest that there may be more than one mechanistic pathway in humans.

GSH depletion has been documented in the rat model.⁵⁸ The dose and route correlated with toxicity and outcome in rodent models of dichloropropene toxicity. At 100 mg/kg in mice, hepatotoxicity occurs by the intraperitoneal route, but not after oral gavage. At 700 mg/kg administered by the intraperitoneal route, hepatic failure and death result.¹¹ The higher dose correlated with a 130 fold increase in dichloropropene epoxide formation. Interestingly, in a rat hepatocyte model, pretreatment with the antioxidant, α -tocopherol, prevented cell death.¹³⁴

Clinical Manifestations

Signs and symptoms of acute oral or inhalational exposure include nausea, vomiting, bloody diarrhea, pancreatitis, hepatotoxicity, tachycardia and hypotension,⁶² dyspnea,⁶⁸ ARDS,⁶² CNS depression,⁸³ acute kidney injury (acute tubular necrosis),⁶² and muscle pain and weakness.⁸³ Coagulopathy and thrombocytopenia, hyperglycemia, severe metabolic acidosis,⁶² and intravascular fluid depletion secondary to hemorrhage are reported. Dermal manifestations include contact hypersensitivity,^{60,138,139} erythema,⁸³ and profuse sweating.⁶² Mucous membrane irritation including erythema, edema, and irritation of the eyes, ears, nose, and throat occurs.^{83,138} Concentrations above 1000 ppm cause lacrimation.¹ Hematologic malignancies including lymphoma and histiocytic lymphoma were reported after prolonged (6 years) dichloropropene exposure.⁸³

Radiographic abnormalities typically lag behind clinical signs. It may take up to 8 hours before abnormalities appear on

chest radiography, even in symptomatic patients.⁶²

Weight loss, hyperemia and superficial ulcerations of the nasal mucosa, inflammation of the pharynx, bleeding from swollen gums,⁸³ liver aminotransferase elevations, and renal function abnormalities¹⁸ are reported after chronic exposure to dichloropropene.

Diagnostic Testing

Liver and kidney function should be monitored following acute poisoning.⁶² No additional or specific tests are recommended beyond those needed for supportive care. Biomonitoring for exposure to dichloropropene is under development.¹⁸ Hepatic γ -glutamyl transpeptidase concentrations are increased in fumigators, but the increase is not statistically significant. However, this finding suggests hepatic enzyme induction. In fumigators, erythrocyte GST and GSH concentrations decreased with increased serum creatinine concentrations and increased urine concentrations of albumin and retinol-binding protein when compared with controls.¹⁸

Treatment

Because of the volatility of dichloropropene, caution should be used to avoid continued inhalational and dermal exposure for both the patient and the health care professional. Symptomatic and supportive care should be provided as for methyl bromide. Following ingestion, oral AC can be administered, but there is no proven value. Orogastric lavage may be appropriate in a patient presenting shortly following ingestion. Exposed eyes should be irrigated with copious amounts of water or 0.9% NaCl solution for at least 15 minutes, and exposed skin should be similarly washed with soap.

There are no data to support specific therapies beyond supportive care, although the use of antioxidant therapy and NAC warrants further study. The patients should be monitored for at least 24 hours after exposure.

SULFURYL FLUORIDE

History and Epidemiology

Sulfuryl fluoride has been used since 1957 as a structural fumigant insecticide to control wood boring insects such as termites in homes. Structure or tent fumigation is performed by completely enclosing a house or other structure in plastic or a tarpaulin, and then sulfuryl fluoride is pumped in as a compressed gas. Chloropicrin is typically added as a warning agent. Although sulfuryl fluoride is commonly used in Florida, California,¹⁰¹ and Washington, a 5-year review of fumigant illness did not contain any reports of sulfuryl fluoride toxicity.²⁰

Toxicokinetics and Toxicodynamics

Sulfuryl fluoride gas is colorless, odorless, and heavier than air. The TLV-TWA for sulfuryl fluoride is 5 ppm; TLV-STEL is 10 ppm; IDLH is 200 ppm.⁹⁹

Little is known about the toxicokinetics of sulfuryl fluoride in humans and the exact mechanism of toxicity is not understood. The respiratory, central nervous, and cardiovascular systems are the primary target organ systems.⁴³ The measurable fluoride concentrations in patients with sulfuryl fluoride poisoning and the development of fluorosis in models of chronic, low concentration exposures suggest that the release of fluoride may be of major pathophysiologic consequence.¹⁰¹ Fluoride complexes with calcium and magnesium, resulting in hypocalcemia and hypomagnesemia (Chap. 107).⁶¹

Clinical Manifestations

Case reports of sulfuryl fluoride exposure describe acute and subacute clinical courses that share many similarities to methyl bromide poisoning. Initial symptoms, especially in limited exposures, may include nausea, vomiting, diarrhea, abdominal pain, cough, and dyspnea. Irritation of mucosal surfaces may produce salivation and nasopharyngitis, lacrimation, and conjunctival injection. CNS manifestations include paresthesias, irritability, agitation, tetany, refractory seizures, and coma. Finally, fluoride toxicity may result in profound shock, cardiac dysrhythmias, wide QRS complexes, prolongation of the QT interval, torsade de pointes, hyperkalemia, and ARDS (Chap. 107).^{101,113}

Memory and dexterity testing were abnormal in structural fumigation workers exposed to both methyl bromide and sulfuryl fluoride.²¹

Diagnostic Testing

Patients with sulfuryl fluoride exposure require monitoring of serum calcium, magnesium, and potassium concentrations. Patients should have an ECG performed and be attached to continuous cardiac monitoring to observe for QRS widening,

QT interval prolongation, and dysrhythmias. Serum fluoride concentrations, although not helpful for acute management, may help as a confirmatory diagnostic test.

Treatment

In patients with inhalational exposure, after removal from the scene to fresh air, the patients should be partially disrobed to avoid further exposure to any liberated sulfuric fluoride gas.

In treating sulfuric fluoride poisoning, aggressive treatment of hypocalcemia with calcium gluconate or calcium chloride may be needed (Antidotes in Depth: A29). Similar to the management of methyl bromide, supportive care may be needed for the seizures, dysrhythmias, bronchospasm, and ARDS. As the fluoride ion is excreted in the urine, fluid resuscitation may be needed to maintain a steady urine output.¹¹⁰

METHYL IODIDE

Iodomethane or methyl iodide is currently under review by the US Environmental Protection Agency. It is proposed as a fumigant to replace methyl bromide. However, several reports from Europe suggest that the toxicity of methyl iodide may be similar to that of methyl bromide.^{39,67} A recent report describes dermal exposure with severe burns and delayed neuropsychiatric sequel, similar to that associated with methyl bromide exposures.²¹

SUMMARY

- Exposure to fumigants may be through ingestion or inhalation depending on the specific fumigant and the physical state.
- The fumigants are associated with multisystem organ failure and, following acute exposure, adversely affect both the cardiovascular and central nervous systems.
- Treatment involves removal from exposure and removal of outer clothing. Dermal decontamination is not generally needed given the volatile nature of most fumigants.
- Staff and patient protection from inhalation is important to prevent iatrogenic toxicity.

112 HERBICIDES

Darren M. Roberts

HISTORY, CLASSIFICATION, AND EPIDEMIOLOGY

An herbicide, any chemical that regulates the growth of a plant, encompasses a large number of xenobiotics of varying characteristics. Herbicides are used around the world for the destruction of plants in the home environment and also in agriculture where weeds are particularly targeted. Poisoning may occur following acute (intentional or unintentional poisoning) or chronic (such as occupational) exposures. Depending on the herbicide and the characteristics of the exposure, this may lead to clinically significant poisoning, including death. This chapter focuses on the most widely used herbicides and also those associated with significant clinical toxicity. In particular, risk assessment and the management of patients with a history of acute herbicide poisoning are emphasized.

Prior to the 1940s, the main method of weed control and field clearance was manual labor, which was time consuming and expensive. A range of xenobiotics were tested, including metals and inorganic compounds; however, their efficacy was limited. The first herbicide marketed was 2,4-dichlorophenoxyacetic acid during the 1940s, followed by other phenoxy acid compounds. Paraquat was marketed in the early 1960s, followed by dicamba later that decade. The development of new herbicides is an active area of research and new herbicides and formulations are frequently released into the market. This includes a number of novel structural compounds for which clinical toxicology data are unavailable. Hundreds of xenobiotics are classified as herbicides and a much larger number of commercial preparations are marketed. Some commercial preparations contain more than one herbicide to potentiate plant destruction. From another perspective, crops are being developed that are resistant to particular herbicides to maximize the selective destruction of weeds without reducing crop production.

Herbicides are the most widely sold pesticides in the world, where in 2007 they accounted for approximately 40% of the total world pesticide market and 48% of the pesticide market in the United States. Home and garden domestic use accounts for 13% of the overall herbicide use in the United States, while the remainder is used in agriculture, government (eg, vegetation control on highways and railways), and industry. In each of the US market sectors, herbicides were four of the top five used pesticides in 2007, including glyphosate, atrazine, acetochlor, and 2,4-dichlorophenoxyacetic acid.³³

Not all herbicide exposures are clinically significant. In developed countries, most acute herbicide exposures are unintentional and the majority of patients do not require admission to hospital. The National Poisoning Database System (NPDS) of the American Association of Poison Control Centers (AAPCC) describes approximately 10,000 herbicide exposures each year. Over the last 12 years, there were approximately five deaths per year and 20 patients per year with clinical outcomes categorized as “major” that were attributed to herbicide poisoning (Chap. 136). Most deaths were due to paraquat and diquat, although recently glyphosate and phenoxy acid compounds are more commonly implicated. Cases of severe poisoning that required hospitalization usually followed intentional self-poisoning. Significant toxicity may also occur with unintentional (eg, storage of a herbicide in food or drink containers) or criminal exposures.

Classification

Hundreds of xenobiotics have herbicidal activity and they may be subclassified by a number of methods. Most commonly they are categorized in terms of their spectrum of activity (selective or nonselective), chemical structure, mechanism of action (contact herbicides or hormone dysregulators), use (preemergence or postemergence), or their toxicity to rats (LD₅₀). Certain xenobiotics are classified as plant growth regulators rather than herbicides, but in this chapter all are considered to be herbicides.

Table 112–1 lists the extensive range of herbicides in current use.⁴⁹ By convention, they are subclassified according to their chemical class and their World Health Organization (WHO) hazard classification. Unfortunately, the utility of these (or any other) methods of classification to predict the hazard to humans with self-poisoning is not proven.

TABLE 112–1. Characteristics of the Major Herbicides Categorized by Chemical Class and WHO Hazard Classification

Contraindications	Pregnancy, relative to paracetamol	II	Acetaminophen, propofol	Propofol induces mild renal toxicity in most cases, but gastrointestinal erosion, ulcers, and death due to respiratory failure are reported. Limited human data for the others.
	In 2017, rifabutin and propofol were among the top 10 antibiotics used in the United States overall, while rifabutin and propofol were among the top 10 used in the domestic sector (children) intravenous assembly	I	Rifabutin (Bimel), rifampin, dexamethasone, rifampicin, erythromycin, propofol, rifabutin	Adverse reactions are reported from rifabutin and erythromycin, which may induce neutropenia and hemolysis with prolonged exposure. In rats, rifabutin induces hepatotoxicity, tumor, and renal impairment to death. Apoptosis, necrosis, and large area of necrosis following intrathecal use of rifabutin. Many of these compounds are poorly absorbed and may be subject to enterohepatic recycling.
Epinephrine	Potentially (particularly local anesthetics)	II	Acetaminophen, Bupivacaine	Limited human data

	Contact herbicide, inhibits photosynthesis inhibits, and/or inhibits carotenoid biosynthesis Atrazine is also an insecticide	U	Atrazine, alachlor, chlorothalopach, oxyfluorfen	
Herbicide glyphosate	Inhibits lipid synthesis	U	Glyphosate, flupropyluron	Limited human data
Isoproturon	Inhibits carotenoid synthesis, interfering with branched amino acid synthesis	U	Isoproturon, metazachlor, metazachlor, metazachlor	Limited human data. In a small case series, isoproturon induced urticaria, respiratory distress, metabolic acidosis, hypotension, and hepatocellular dysfunction
Isoproturon	Nonselective	U	Isoproturon	Nausea, vomiting, diarrhea, metabolic acidosis, kidney failure, hemolysis, methemoglobinemia, rhabdomyolysis, and disseminated intravascular coagulation. In animal studies hemolysis and methemoglobinemia and plasma hemolysis. Methemoglobinemia is usually responsive to methylene blue (a single report suggested benefit when used within 1 hour of exposure ¹⁰) but when thrombocytopenia has been noted
Metolachlor	Phenylalanine, selective for glycine inhibits photosynthesis, a photosynthetic and/or inhibition of cell wall synthesis, synthesis Lampricide (chlorinated with phenylalanine and inorganic)	U U U	Aminocyclopropane Bromoxynil, isoproturon Dichlorodimethyl	Limited human data Limited human data. In animal, it inhibits carotenoid biosynthesis and urticaria (25 toxicity may be prevented by DOP)
Disinfectant Disinfectant	Disinfectant (broad-spectrum)	U	Disinfectant, DMC (4,4-dimethyl-2-oxo-1,3-dioxane)	Limited human data. methemoglobinemia is reported in animal. Disinfectant inhibits carotenoid biosynthesis
Organic phosphorus	Respiratory phosphorus, selective for glycine Glyphosate and glyphosate are nonselective post- emergence herbicides In 2007, glyphosate was the most used pesticide in the United States and the second most used in the domestic sector Glyphosate and glyphosate inhibit photosyn- thesis, biosynthesis, lipid synthesis, and glycine inhibits PEP synthase, which interferes with amino acid synthesis	U U U	Glyphosate, glyphosate (broad-spectrum), alachlor, isoproturon, glyphosate Glyphosate Isoproturon, glyphosate	Limited human data. Glyphosate is metabolized to glyphosate in plants, but in humans only the metabolite 3-amino-4-hydroxyphenyl phosphonic acid has been found. Clinical effects of poisoning include apnea, anemia, and metabolic acidosis. Inhibitors and biosynthesis are known to inhibit amino acid biosynthesis See text for glyphosate and Fig. 13-1 See text for glyphosate and Fig. 13-1. Limited human data for isoproturon

attributed to the surfactant nonylphenol ethoxylate used in this product, which has an LD₅₀ of 75 mg/kg IP. In vitro studies with a number of formulations demonstrate increased cardiovascular toxicity compared with the technical herbicides.¹³ Similarly, coformulants increase the in vitro toxicity from phenoxyacetic acid derivatives and glufosinate.

Impurities may also be generated during manufacture or storage of the herbicide formulation, which can contribute to toxicity. For example, phenolic byproducts from the manufacture of phenoxyacetic acid herbicides may be found as impurities in commercial formulations. Some proprietary products contain a combination of herbicidal compounds that probably have additive effects, further complicating the risk assessment of an acute exposure.

Epidemiology

The incidence of poisoning with individual herbicides depends on their availability. Availability is associated with local marketing practices and is reflected in sales in the domestic sector. For example, paraquat poisonings are now rare in the United States, while the incidence of glyphosate poisoning has increased. Similarly, after paraquat was banned in Japan in the late 1980s there was an increase in the number of glufosinate poisonings.

Herbicide poisoning is a major issue in developing countries of the Asia-Pacific region where subsistence farming is common and herbicide use is relatively high. By contrast, the incidence of severe herbicide poisoning is less in developed countries because the population is concentrated in urban areas where access is limited to lower toxicity herbicides that are sold in smaller volumes as diluted formulations intended for household use (Chaps. 113 and 137).

Regulatory and Considerations

When properly used, most herbicide formulations have a low toxic potential for applicators because they are poorly absorbed across the skin and respiratory membranes. When inappropriately used, in particular when there is enteral (or rarely parenteral) exposure, toxicity is more pronounced.

The toxicity of herbicides varies among individual xenobiotics, but as a group, they appear to be intrinsically more toxic than medications when ingested with suicidal intent. Restrictions of the availability and formulation of toxic herbicides by regulatory authorities may improve outcomes from herbicide poisoning. For example, in the context of self-poisoning, the replacement of highly toxic pesticides with less toxic compounds can decrease the overall mortality⁹⁷ without altering agricultural outputs.⁷² Prospective cohort studies have been useful for estimating the case fatality of individual herbicides in the context of intentional self-poisoning, particularly when encountered in the same clinical environment. For example, in Sri Lanka the following herbicide case fatalities are reported: fenoxaprop-P-ethyl, 0%¹³²; bispyribac, 1.8%³⁰; glyphosate, 3.2%¹⁰⁰; 4-chloro-2-methylphenoxyacetic acid (MCPA), 4.4%⁹⁸; propanil, 10.7%⁹⁹; and paraquat, 50% to 70%.¹²⁸ This information is of interest to regulatory authorities in their control of the marketing, sales, and formulation of herbicides.

Regulatory bodies must also consider other factors, including the cost and efficacy of herbicides and their fate in the environment. An ideal herbicide is one that is selective for the target plant and does not migrate far from the site of application. Selective targeting can occur when the herbicide is rapidly inactivated or binds strongly to soil components. For example, paraquat and glyphosate are inactivated when they contact soil, which is favorable because they remain in the region of application. By contrast, atrazine is more mobile, allowing it to leach into groundwater and migrate great distances. While the concentration of atrazine at distant sites is low, there is concern that it has the potential to alter the growth and development of nontarget plants and animals.¹⁰⁴

GENERAL COMMENTS FOR THE MANAGEMENT OF ACUTE HERBICIDE POISONING

Diagnosis

Herbicide poisoning is diagnosed following a specific history or other evidence of exposure (such as an empty bottle) and associated clinical symptoms. A detailed history, including the type of herbicide, amount, time since poisoning, and symptoms, is essential. It is necessary to determine the actual brand in many cases due to variability in salts, concentrations, and coformulants. Further, in some cases it is also necessary to determine the specific type of a brand; for example, the product called Roundup contains glyphosate but it is sold in different formulations worldwide within market sectors.

Depending on local laboratory resources it may be possible to confirm the diagnosis with a specific assay, such as paraquat and glufosinate, but these are not usually available in a clinically meaningful timeframe.

The low incidence of herbicide poisoning in some regions may mean that it is not considered in the differential diagnosis when a history is not available. Therefore, a high index of suspicion is necessary and clinicians should be familiar with the features of herbicide poisoning.

The pathophysiology of acute herbicide poisoning, and therefore the clinical manifestations, varies between individual compounds. Some herbicides induce multisystem toxicity due to interactions with a number of physiologic systems. The mechanism of toxicity and pathophysiological changes in humans are discussed below for each herbicide individually.

Initial Management

An accurate risk assessment is necessary for the proper triage and subsequent management of patients with acute herbicide poisoning. Risk assessment involves consideration of the dose ingested, time since ingestion, clinical features, patient factors, and availability of medical facilities. All intentional exposures should be considered significant. If a patient presents to a facility that is unable to provide sufficient medical and nursing care or does not have ready access to necessary antidotes, then arrangements should be made to rapidly and safely transport the patient to a health care facility.

For many herbicides the initial management of an acute poisoning follows standard guidelines. All patients should receive prompt resuscitation emphasizing the airway, breathing, and circulation. Gastrointestinal toxicity, such as nausea, vomiting, and diarrhea, is common, leading to salt and water depletion that requires the administration of antiemetics and intravenous fluids.

Gastrointestinal decontamination may decrease absorption of the herbicide from the gut, reducing systemic exposure. Gastric lavage is generally not recommended in acute poisoning because patients usually present too late or have self-decontaminated from vomiting and diarrhea. Lavage has been used by some practitioners for patients presenting shortly after an ingestion of a liquid formulation for which treatment options are limited. Depending on the procedure used, this treatment may cause harm and should only be conducted by an experienced clinician when the airway is protected. Ingestion of a corrosive product is a relative contraindication. Oral activated charcoal may be given if the patient presents within 1 to 2 hours of ingestion of an herbicide known to cause significant poisoning. In the case of some herbicides there is prolonged absorption (eg, propanil, MCPA), so later administration of activated charcoal may be reasonable.

Specific antidotes are available for only a few herbicides, which reflect their ill defined mechanisms of toxicity.

Extracorporeal techniques, including hemoperfusion and hemodialysis, may decrease the systemic exposure by increasing the rate of elimination. The role of these treatments is discussed below for each pesticide.

Dermal decontamination is necessary if the patient has incurred cutaneous exposure. The patient should be washed with soap and water and contaminated clothes, shoes, and leather materials should be removed and safely discarded.

Laboratory investigations may be useful for determining the evolution of organ toxicity, including serial measurement of liver and kidney function, electrolytes, and acid–base status. Abnormalities should be corrected where possible. Respiratory distress and hypoxia with focal respiratory crackles soon after presentation are likely to result from aspiration pneumonitis, which can be confirmed on chest radiography.

Patients with a history of acute ingestion should be observed for a minimum of 6 hours. Patients with a history of intentional ingestion and gastrointestinal symptoms should be observed for at least 24 hours depending on the herbicide given that clinical toxicity may progress or be delayed in some cases.

Occupational and Secondary Exposures (Including Nosocomial Poisoning)

Concern has been expressed regarding the risk of nosocomial poisoning to staff and family members who are exposed to patients with acute herbicide poisoning. However, the risk to health care staff providing clinical care is low compared with other occupations, such as agricultural workers in whom toxicity is rarely observed. Universal precautions employing nitrile gloves are most likely to provide sufficient protection for staff members.

Few cases of secondary poisoning, if any, have been confirmed, and effects in these potentially exposed individuals were generally mild, such as nausea, dizziness, weakness, and headaches, probably relating to inhalation of the hydrocarbon solvent. These symptoms usually resolve after exposure to fresh air. Biomarkers for monitoring occupational exposures, as in the case of pesticide applicators, are outside the scope of this chapter.

Amide Compounds, Particularly Anilide Derivatives

Anilide compounds are the most widely used amide herbicides, of which propanil (3'4'-dichloropropionanilide {DCPA}), alachlor (2-chloro-2',6'-diethyl-N-methoxymethylacetanilide), and butachlor (N-butoxymethyl-2-chloro-2',6'-diethylacetanilide) are particularly common. Other amide herbicides and available toxicity data are listed in [Table 112–1](#). In 2007, acetochlor, propanil, metolachlor, and dimethenamid were among the top herbicides used in the United States.³³ Anilide compounds are selective herbicides used mostly in rice cultivation in many parts of the world. Acute self-poisoning is reported particularly in Asia where subsistence farming is common. Data are limited for most compounds, except for propanil, butachlor, metachlor, and alachlor. The case fatality of propanil exceeds 10% compared with a combined mortality of less than 3% for butachlor, metachlor, and alachlor. Poor outcomes may reflect the inadequacies of current treatment regimens.

Pharmacology

Most of the clinical manifestations of propanil poisoning are mediated by its metabolites. 3,4-Dichlorophenylhydroxylamine is the most toxic metabolite and it directly induces methemoglobinemia and hemolysis in a dose-related manner. 3,4-Dichlorophenylhydroxylamine is cooxidized with oxyhemoglobin (Fe^{2+}) in erythrocytes to produce methemoglobin (Fe^{3+} ; Chap. 127).

However, toxicity may not be solely attributed to methemoglobinemia. Isolated methemoglobin levels exceeding 50% are usually required for fatal outcomes, but fatal propanil poisoning is reported with methemoglobin levels as low as 40%.^{17,86,129,130} Therefore, other toxic mechanisms may contribute to clinical outcomes. Rats show signs of toxicity despite inhibition of the hydrolytic enzymes that metabolize propanil (Fig. 112–1) and in the absence of methemoglobinemia, supporting direct toxicity from propanil itself.¹¹⁵ Coformulants may also contribute.

FIGURE 112–1 Structures of common anilide compounds and the bioconversion of propanil.

The hydroxylamine metabolite depletes glutathione, which may induce toxicity, although this is not consistently reported. Other possible toxicities from the metabolism of propanil include nephrotoxicity, lipoperoxidation, myelotoxicity, and immune dysfunction; the significance of these toxicities is poorly defined.

Para-hydroxylated aniline and other compounds are products of alachlor, butachlor, and acetochlor (2-chloro-N-ethoxymethyl-6'-ethylacet-o-toluidide) metabolism and may reduce glutathione and induce hepatotoxicity or cancer, particularly in rats.

Pharmacokinetics and Toxicokinetics

Absorption is rapid in animals, with a peak serum concentration expected one hour postingestion. The volume of distribution (V_d) of propanil has not been determined, but is expected to be large given that both propanil and 3,4-dichloroaniline are highly lipid soluble. This V_d is consistent with data in the channel catfish where uptake and distribution of propanil were noted to be extensive. Anilide compounds interact with adenosine triphosphate (ATP)-binding cassette transporters, which may also influence the kinetics.

Anilide compounds undergo sequential metabolic reactions that produce toxic xenobiotics (Fig. 112–1). The first reaction is hydrolysis of the anilide to an aniline compound. This reaction is catalyzed by an esterase known as arylamidase, which has a high capacity in humans compared to rats ($K_m = 473 \mu\text{M}$ and $271 \mu\text{M}$, respectively) and sometimes by the cytochrome P450 system. Examples include the bioconversion of propanil to 3,4-dichloroaniline and also conversion of alachlor and butachlor to 2,6-diethylaniline. These aniline intermediates are then oxidized by cytochrome P450, although the responsible isoenzyme has not been determined. N-hydroxylation of 3,4-dichloroaniline produces the hydroxylamine compound that induces hemolysis and methemoglobinemia, which are the most obvious manifestations of propanil poisoning.^{76,77,115}

These bioactivation reactions appear to be fairly rapid, whereas 3,4-dichloroaniline and methemoglobin are formed

within 2 to 3 hours of parenteral administration of propanil to animals. The hydroxylation of 3,4-dichloroaniline may be saturable ($K_m = 120 \mu\text{M}$ in rats) and slower than arylamidase, leading to a prolonged elimination of 3,4-dichloroaniline following large exposures. In the case of alachlor, butachlor, and acetochlor, parahydroxylated aniline compounds are produced, which appear to be carcinogens in rats.

These metabolic reactions are similar to those of dapsone, which are well characterized: the severity of methemoglobinemia relates to the amount of the dapsone hydroxylamine, which varies with dose, and cytochrome P450 activity ([Chap. 127](#)).

Propanil displays nonlinear toxicokinetics in humans with prolonged absorption continuing for approximately 10 hours following ingestion. Bioconversion to 3,4-dichloroaniline occurs largely within 6 hours, although it is particularly variable, which may reflect interindividual differences in esterase activity, dose, or coexposure to cholinesterase inhibitors.⁹⁹ The median apparent elimination half-life of propanil is 3.2 hours compared with 3,4-dichloroaniline, which has a highly variable elimination profile. In general, the concentration of 3,4-dichloroaniline exceeds that of propanil and remains elevated for a longer period.⁹⁹ In a case of coingestion of carbaryl, the peak 3,4-dichloroaniline concentration was observed at 24 hours,⁴² while in a fatal case the concentration of 3,4-dichloroaniline continued to increase until at least 30 hours postingestion.⁹⁹ By 36 hours postingestion the concentration of 3,4-dichloroaniline is low in survivors, so clinical toxicity is unlikely to increase beyond this time.⁹⁹

Pathophysiology

The predominant clinical manifestation in acute poisoning is methemoglobinemia. Methemoglobin is unable to bind and transport oxygen, inducing a relative hypoxia at the cellular level despite adequate arterial oxygenation. This leads to end-organ dysfunction, including central nervous system depression, hypotension, and acidemia. Because the plasma concentration of 3,4-dichloroaniline remains elevated, methemoglobinemia persists for a similar time.^{42,86,129} Sedation due to the direct effect of propanil or a hydrocarbon coformulant solvent may cause hypoventilation, which contributes to cellular hypoxia. Failure to correct these abnormalities may lead to irreversible injury and death.

Clinical Manifestations

Methemoglobinemia, hemolysis and anemia, coma, and death are reported following acute propanil poisoning. These occur in the clinical context of cyanosis, acidemia, and progressive end-organ dysfunction. A case fatality as high as 10.7% is reported and the median time to death was 36 hours. Patients who die tend to be older with a depressed Glasgow Coma Scale score and elevated concentration of propanil. Nausea, vomiting, diarrhea, tachycardia, dizziness, and confusion are also reported in patients who do not develop severe poisoning.⁹⁹

Alachlor, metachlor, and butachlor appear to be less toxic than propanil, with a case fatality less than 3% with self-poisoning.^{71,112} The manifestations of acute poisoning are usually mild, including gastrointestinal symptoms, agitation, dyspnea, and abnormal liver enzymes.^{71,112} Major symptoms include seizures, rhabdomyolysis, acidemia, kidney failure, and cardiac dysrhythmias; hypotension and coma preceded death.^{71,112} Methemoglobinemia was not reported in these studies. Hepatic dysfunction was reported following dermal occupational exposure to butachlor.

Cyanosis was reported following acute ingestion of mefenacet (2-benzothiazol-2-yloxy-N-methylacetanilide) and imazosulfuron (1-{2-chloroimidazo(1,2-a) pyridin-3-ylsulfonyl}-3-{4,6-dimethoxypyrimidin-2-yl}urea) in the context of normal cooximetry. This was attributed to formation of a green pigment (green-colored urine was also reported) and no other symptoms of toxicity were observed.¹¹⁴

Acute metolachlor (2-chloro-N-{6-ethyl-o-tolyl}-N-{(1RS)-2-methoxy-1-methylethyl}acetamide) poisoning in goats induced predominantly neuromuscular symptoms, including tremors, ataxia, and myoclonus, which progressed rapidly to death. Kidney and hepatocellular toxicity were also noted. Acute acetochlor exposures in rats induced methemoglobinemia and hepatocellular toxicity.

Diagnostic Testing

Patients with a history of propanil poisoning should be investigated for the presence of methemoglobinemia ([Chap. 127](#)).

While the concentrations of propanil and 3,4-dichloroaniline appear to reflect clinical outcomes, this relationship is less marked for 3,4-dichloroaniline during the first 6 hours, which probably relates to the time for bioconversion from propanil.⁹⁹ However, propanil and 3,4-dichloroaniline assays are not commercially available and this observation has not been validated. Further, the relationship between concentration and outcomes may depend on patient comorbidities.

Management

The minimum toxic dose has not been determined and the potential for severe poisoning and death is high, so all patients with herbicide ingestions should be treated as significant and monitored for a minimum of 12 hours. Patients with

symptomatic ingestions should be treated cautiously, including continuous monitoring for 24 to 48 hours, preferably in an intensive care unit.

Routine clinical observations are sufficient to detect signs of poisoning, in particular, sedation and clinical cyanosis. Until more data are available it seems reasonable to focus treatment on reversal of methemoglobinemia. There is sufficient time to initiate specific treatments in propanil poisoning given that clinical signs of poisoning are noted early postingestion, yet the time to death is usually greater than 24 hours. There are no controlled clinical or laboratory data available on the effect of any specific treatment in acute symptomatic propanil poisoning, so management is largely empirical.

Resuscitation and Supportive Care. Prompt resuscitation and close observation are required in all patients. Patients should be monitored clinically including pulse oximetry, and receive supportive care including supplemental oxygen, intravenous fluids, and ventilatory and hemodynamic support as required. In the absence of cooximetry analysis, significant methemoglobinemia should be suspected when cyanosis does not correct with high-flow oxygen and ventilatory support. Bedside visual assessment, using blood added to absorbent paper, is an accurate method to quantify the degree of methemoglobinemia¹¹³ Euglycemia should be ensured since adequate glucose concentrations are required for reversal of methemoglobin

Hemoglobin concentrations should be monitored to detect hemolysis, and folate supplementation may be necessary during the recovery phase if anemia is significant.

Gastrointestinal Decontamination. Toxicokinetic studies of propanil have demonstrated a prolonged absorption phase, so it is reasonable to administer activated charcoal to the patient a number of hours postingestion

Extracorporeal Removal. Treatment with combined hemodialysis and hemoperfusion was associated with a propanil elimination half-life of one hour, although clearance was not directly measured⁸⁶ However, half-lives as short as one hour have been reported in patients who have not received this treatment⁹⁹ so its efficacy remains unknown. Exchange transfusion has the potential to decrease the concentration of propanil and free hemoglobin, while replacing reduced hemoglobin and hemolyzed erythrocytes. However, the function of transfused erythrocytes is temporarily impaired posttransfusion because of depletion of 2,3-bisphosphoglycerate during storage. Further, transfusion reactions such as acute respiratory distress syndrome may occur, which is of concern when oxygenation is already impaired. In the absence of controlled studies, the role of such treatments in the routine management of acute propanil poisoning is poorly defined (Chap. 10).

Antidotes. Antidotes are largely used for the treatment of methemoglobinemia. Methylene blue (Antidotes in Depth: A41) is considered the first-line treatment for methemoglobinemia. Methylene blue has a half-life of 5 hours, which is commonly shorter than that of 3,4-dichloroaniline, so rebound poisoning (ie, an increase in methemoglobin following an initial recovery postadministration of methylene blue) is anticipated and has been observed with a bolus regimen. This may be prevented by administration of methylene blue as a constant infusion

Other potential treatments include toluidine blue, N-acetylcysteine, ascorbic acid, and cimetidine, but no clinical studies have assessed the role of these potential antidotes in the management of propanil poisoning.

BIPYRIDYL COMPOUNDS, PARAQUAT AND DIQUAT

Bipyridyl compounds are nonselective contact herbicides. The most widely used is paraquat (1,1'-dimethyl-4,4'-bipyridinium), but diquat (1,1'-ethylene-2,2'-bipyridylium) is also commonly used (Fig. 112-2). Paraquat is one of the most toxic pesticides available. Ingestion of as little as 10 to 20 mL of the 20% wt/vol solution is sufficient to cause death. Overall, the mortality rate varies between 50% and 90%; however, in cases of intentional self-poisoning with concentrated formulations, mortality approaches 100%. An increasing number of countries are banning the sale of paraquat in view of its high toxicity. Diquat is less toxic than paraquat, so it may be coformulated with paraquat (allowing a lower concentration of paraquat) or used as an alternative in countries where paraquat is severely restricted. Because more data are available on paraquat than diquat, much of the following discussion and information relates particularly to paraquat.

FIGURE 112-2 Structures of paraquat and diquat.

Pharmacology

Paraquat and diquat formulations are highly irritating and often corrosive, causing direct injury. Paraquat induces intracellular toxicity by the generation of reactive oxygen species that nonspecifically damage the lipid membrane of cells, inducing cellular injury and death. Once paraquat enters the intracellular space it is oxidized to the paraquat radical. This radical is subsequently reduced by diaphorase in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) to re-form the parent paraquat compound and superoxide radical, a reactive oxygen species. This process is known as redox cycling (Fig. 112–3). The superoxide radical is susceptible to further reactions by other intracellular processes, leading to formation of other reactive oxygen species, including hydroxyl radicals and peroxynitrite. Reactive oxygen species are potent cytotoxics. Paraquat redox cycling continues as long as NADPH and oxygen are available. Depletion of NADPH prevents recycling of glutathione and interferes with other intracellular processes, including energy production and active transporters, exacerbating toxicity. Intracellular protective mechanisms, such as glutathione, superoxide dismutase, and catalase, are overwhelmed or depleted following large exposures. Taken together, these cytotoxic reactions induce cellular necrosis, which is followed by an influx of neutrophils and macrophages. The reactions contribute to the inflammatory response and promote fibrosis and destruction of normal tissue architecture over a number of days.^{18,22}

FIGURE 112–3 Toxicology of paraquat (PQT) and proposed mechanisms of action of potential treatments. Antioxidants include vitamins C and E and glutathione donors (particularly N-acetylcysteine, S-carboxymethylcysteine). PQT• = paraquat radical; NO• = nitric oxide; ONOO• = peroxynitrite; OH• = hydroxyl radical.

Supplemental oxygen probably increases the generation of reactive oxygen species.

Pharmacokinetics and Toxicokinetics

Absorption is limited following dermal exposures, although prolonged exposures (at least several hours) to concentrated formulations may degrade the epithelial barrier, allowing some systemic absorption. Absorption across the respiratory epithelium is limited.

The oral bioavailability of paraquat varies among animal species, but overall it is low (< 10%). The bioavailability of paraquat in humans is estimated to be less than 5%,¹⁶ yet an oral exposure of as little as 10 mL of the 20% wt/vol formulation allows sufficient paraquat to be absorbed for significant poisoning to occur. Absorption is rapid and the peak concentration occurs within one hour. Coingestion of food may decrease the absorption of paraquat. Recently, paraquat was reformulated with an increased emetic along with an alginate (Gramoxone Inteon) that formed a gelatinous mixture on contact with gastric acid, limiting release of the paraquat into the stomach. This formulation reduced paraquat absorption in animals³⁷ and initially appeared to improve outcomes from self-poisoning in humans (mortality of 64% compared with 74% with the standard preparation),¹²⁶ but it may not have been sustained.¹²⁸

Paraquat binds minimally to plasma proteins. Paraquat and diquat rapidly distribute to all tissues where they accumulate but may redistribute back to the central circulation.⁸⁴ In humans the distribution half-life is approximately 5 hours. Paraquat is taken up by alveolar cells through an active energy-dependent polyamine transporter. Paraquat accumulates in alveolar cells, peaking at around 6 hours postingestion in patients with normal kidney function; this may be delayed in the context of kidney impairment.⁵ Paraquat slowly redistributes from the lungs into the systemic circulation as the plasma concentration falls, which may reflect impaired pneumocyte function from acute respiratory distress syndrome. By contrast, diquat uptake occurs to a limited extent.

Paraquat and diquat are not metabolized and elimination is primarily renal with more than 90% of a dose being excreted within the first 24 hours of poisoning if kidney function is maintained.⁴⁵ Its clearance initially exceeds that of creatinine because of active secretion and also through increased renal blood flow.¹² Renal clearance may be reduced by exogenous compounds or an acidic urine pH.¹² Impaired kidney function is commonly reported with paraquat and diquat poisoning, which decreases excretion and potentiates poisoning. Elimination is prolonged in this setting with a terminal half-life of around 80 hours in humans.⁴⁵ Paraquat is detected in the urine of surviving patients beyond 30 days despite plasma concentrations being quite low 48 hours postingestion.³ In animals, the terminal elimination half-life of paraquat is more than 50 hours.⁸⁴

Pathophysiology

Paraquat induces nonspecific cellular necrosis. Lung and kidney injuries are prominent in acute paraquat poisoning because of the high concentrations found in these cells.

Acute pneumonitis and hemorrhage, followed by ongoing inflammation and progressive pulmonary fibrosis, reduces oxygen diffusion and induces dyspnea and hypoxia, which interferes with normal cellular function.²²

Paraquat induces acute tubular necrosis due to direct toxicity to the proximal tubule in particular, and to a lesser degree distal structures. Other factors contributing to the development of acute kidney injury include hypoperfusion from hypovolemia and/or hypotension and direct glomerular injury. Varying degrees of oliguria, proteinuria, hematuria, and glycosuria are reported.¹² Acute kidney impairment interferes with normal fluid and electrolyte homeostasis, as well as interfering with paraquat elimination, which promotes systemic toxicity.

Necrosis of the gastrointestinal tract limits intake and causes fluid shifts that contribute to hypotension induced by direct vascular toxicity. Hypotension impairs tissue perfusion and if uncorrected progresses to irreversible shock. Failure to correct these abnormalities may lead to irreversible organ injury and death.

Clinical Manifestations

Topical exposures may induce painful irritation to the eyes and skin, progressing to ulceration or desquamation depending on the concentration of the solution, duration of exposure, and adequacy of decontamination. Intravenous administration induces severe poisoning from small exposures.

Most ingestions of bipyridyl compounds induce poisoning, where ingestion of as little as 5 mL of paraquat 20% wt/vol can cause death in more than 50% of cases. Gastrointestinal toxicity occurs early, including nausea, vomiting, and abdominal and oral pain. Diarrhea, ileus, and pancreatitis are also reported. Necrosis of mucous membranes (occasionally referred to as pseudodiphtheria¹¹⁷) and ulceration are prominent symptoms that occur within 12 hours. Oromucosal injury has been observed following brief oral exposures without swallowing. Dysphagia and odynophagia follow larger exposures and may progress to esophageal rupture, mediastinitis, subcutaneous emphysema, and pneumothorax, which are preterminal events. Death is more likely in those patients who experience a peripheral burning sensation.²⁹

Respiratory symptoms are prominent in paraquat poisoning, including acute respiratory distress syndrome manifesting as dyspnea, hypoxia, and increased work of breathing. Ingestions of greater than 50 mL of 20% wt/vol formulation causes multiorgan dysfunction with rapid onset of death within days of ingestion in most patients. Features include hypotension,

acute kidney and liver injury, severe diarrhea, and hemolytic anemia.

By contrast, acute lung injury is less marked with diquat ingestion or following smaller exposures of paraquat (< 15–20 mL of 20% wt/vol formulations). In the case of paraquat the acute respiratory impairment may be followed by progressive pulmonary fibrosis and death weeks or months postingestion. Varying degrees of acute kidney injury and hepatic dysfunction can also occur.^{6,48} Acute kidney injury peaks around 5 days postingestion and resolves within 3 weeks in survivors.⁵⁴ Paraquat-induced pulmonary injury can resolve to near-normal function over months to years in survivors.⁶⁶

Diquat does not concentrate in the pneumocytes as readily as paraquat. Therefore, if the patient survives the multiorgan dysfunction, pulmonary fibrosis is less likely to occur.¹³¹ Seizures are reported with diquat poisoning and uncommonly with paraquat.

Ingestion of the adjuvant for Gramoxone Inteon can induce minor gastrointestinal symptoms, an elevated serum osmolar gap and metabolic acidosis with hyperlactatemia, but outcomes are favorable.⁸⁰

Diagnostic Testing

Paraquat poisoning is diagnosed when there is a history of exposure and the clinical symptoms, so a high index of clinical suspicion is required. Differential diagnoses include other corrosive exposures, sepsis, or other cellular poisons such as phosphine, colchicine, or iron.

The presence of a bipyridyl compound in blood confirms exposure but availability of these assays is increasingly limited. The urinary dithionite test is a simple and quick method for confirming (or excluding) paraquat and diquat poisoning. Various methods are reported, including the addition of 1 g of sodium bicarbonate and 1 g of sodium dithionite, or 1 to 2 mL of 1% sodium dithionite in 1 to 2 M sodium hydroxide, to 10 mL of urine. A color change (blue for paraquat and green for diquat) confirms ingestion—the darker the color, the higher the concentration.^{3,58,103} If the test is negative on urine beyond 6 hours after ingestion, a large exposure is unlikely, but repeat testing should be conducted over 24 hours. The dithionite test can also be conducted on plasma (eg, add 200 μ L of 1% sodium dithionite in 2 M sodium hydroxide to 2 mL plasma from the patient), whereas a positive result is specific for death, but a negative test does not exclude severe poisoning or death.⁵⁸

Given that outcomes from paraquat poisoning are generally poor, diagnostic tests may help differentiate patients who may survive from those in whom death is almost certain. The dose of paraquat is a well-established predictor of death, although this information may not be accurately known at the time of admission. Investigations in patients with acute paraquat poisoning have attempted to determine the severity of poisoning and better define prognosis. Unfortunately, few have been validated so their predictive ability is unconfirmed. A range of prognostic tests has been reviewed²⁴ and a selection of these are discussed below.

Quantitative analysis of the concentration of paraquat in plasma is useful for prognostication, and a number of similar nomograms have been developed to assist with this process (Fig. 112–4). The paraquat concentration must be interpreted relative to the time since ingestion and each method performs similarly.¹¹⁰ The Severity Index of Paraquat Poisoning (SIPP) can also be calculated with this information, by multiplying the plasma concentration (mg/L) by the time since ingestion (hours). Here, SIPP less than 10 predicts survival, SIPP 10 to 50 predicts death from lung fibrosis, and SIPP more than 50 predicts death from circulatory failure.¹⁰⁷ Determination of the concentration of paraquat in the urine of exposed patients also predicts outcomes. Barriers to the use of these methods include the limited availability of quantitative paraquat assays (leading to a long turnaround time) and the accuracy of the time of ingestion.

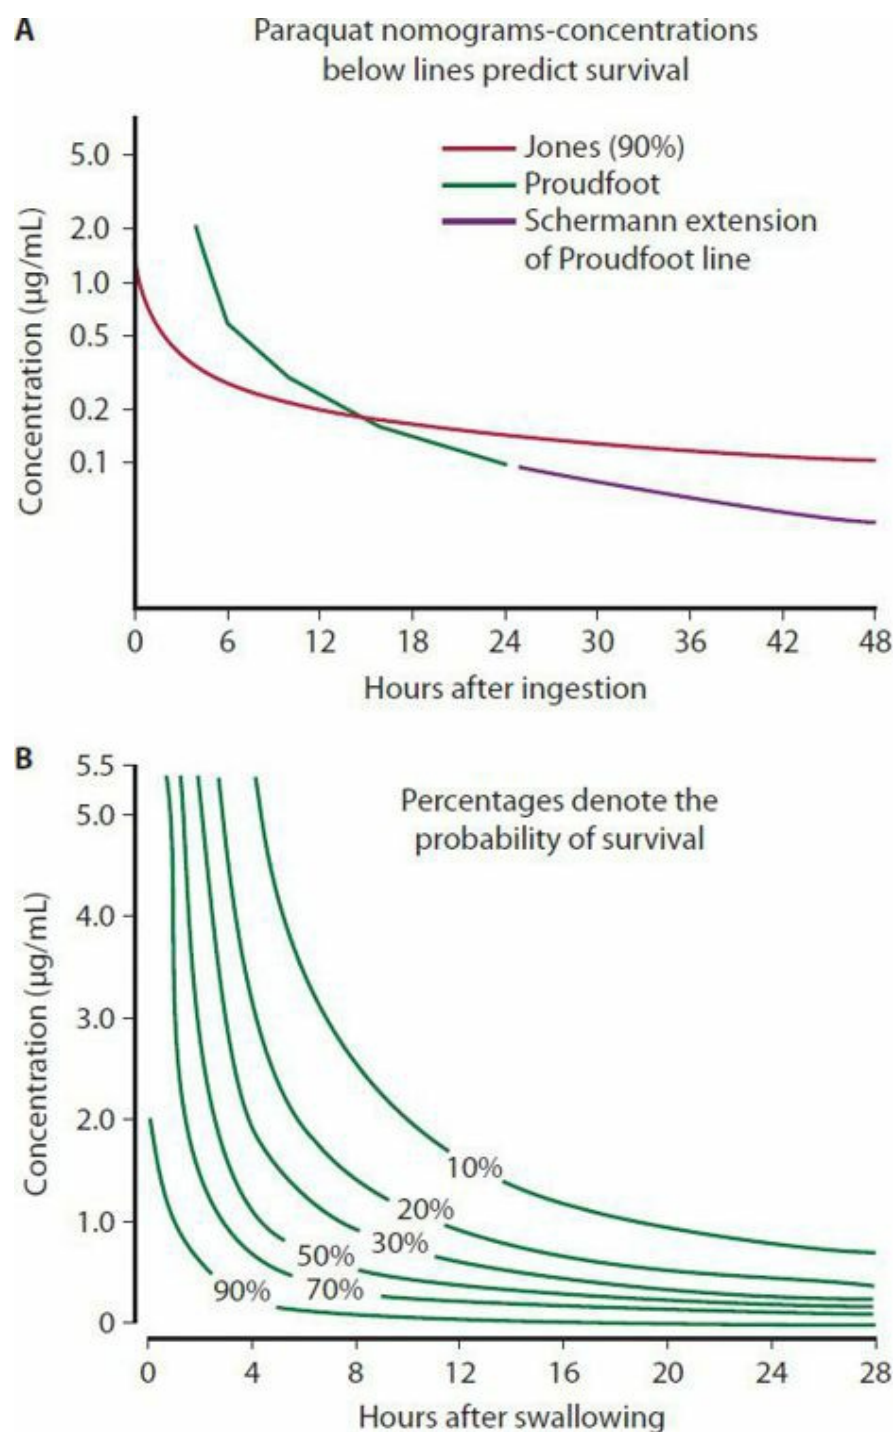

FIGURE 112-4 Nomograms for plasma paraquat concentrations. (A) Compilation of three nomograms proposed by Proudfoot et al,⁹⁴ Scherrmann et al,¹⁰⁸ and Jones et al.⁵² (B) Hart paraquat nomogram.³⁶ In A, concentrations below lines predict survival. In B, lines link concentrations of equal probability of survival. (Reproduced with permission from Eddleston M, Wilks MF, Buckley NA. Prospects for treatment of paraquat-induced lung fibrosis with immunosuppressive drugs and the need for better prediction of outcome: a systematic review, *QJM* 2003;96(11):809–824.)

Other methods for predicting outcomes from paraquat poisoning have used combinations of simple laboratory tests including blood gas analysis, complete blood count, electrolytes, kidney function, and liver function tests.²⁴ Various specific changes have been proposed to predict death (eg, metabolic acidosis with hyperlactatemia), but few have been validated. In general, any abnormal result raises the suspicion of a significant poisoning.

A raised admission creatinine concentration predicts death but is neither sensitive nor specific, although the higher the creatinine concentration, the higher the risk of death.^{31,54,58,102}

The rate of increase in creatinine concentration is a simple and practical test to predict prognosis. An increase less than 0.03 mg/dL/h (3 $\mu\text{mol/L/h}$) over 5 hours predicts survival,⁹⁵ or greater than 0.05 mg/dL/h (4.3 $\mu\text{mol/L/h}$) over 12 hours (sensitivity 100%, specificity 85%, likelihood ratio 7) predicts death.¹⁰² A similar relationship was noted for cystatin C, where a rate of increase in cystatin C greater than 0.009 mg/L/h over 6 hours (sensitivity 100%, specificity 91%, likelihood ratio 11) predicted death.¹⁰² This method of prognostication is advantageous because the rate of increase can be determined irrespective of the time of poisoning. Paraquat and diquat interfere with creatinine assays using the Jaffe method, but this is mostly an issue with concentrations exceeding 100 mg/L, which are rarely observed and likely to be associated with severe

clinical toxicity.⁹²

Other biomarkers of kidney function have been explored but their role in clinical management is not confirmed nor did they improve on existing methods.

Management

Because death can occur following ingestion of as little as 5 mL of the 20% wt/vol paraquat, all exposures should be treated as potentially life threatening. Patients suspected of ingesting paraquat should be observed in hospital for at least 6 hours postingestion or until a urinary dithionite test can be conducted.

Many medical interventions have been proposed for the treatment of patients with acute paraquat poisoning but data supporting their efficacy are lacking; dose–response studies for most of these interventions are also unavailable.

Given the high likelihood of death from acute paraquat poisoning, many publications report concurrent administration of a number of therapies in the hope of a benefit, including activated charcoal, acetylcysteine, vitamins C and E, immunosuppressants, and hemodialysis and/or hemoperfusion. The literature is complicated by case reports describing survival in patients who were administered one or a combination of therapies, despite apparently poor prognosis. Various other treatments have been studied in animals including pirfenidone, complement inhibition, p-sulfonatocalix-[4]arene, dimercaptopropane sulfonate, ambroxol, and selenium, but human data are lacking.

The choice of which interventions should be administered to a patient is best made on a case-by-case basis by the treating physician in consultation with relevant resources. Detailed discussion with the patient and relatives early in the presentation is recommended to determine their preference for treatment modalities in the context of the estimated prognosis (see above). In general, a comprehensive treatment regimen is reasonable in patients who present very early (within 2 hours of poisoning) or those with a faintly positive dithionite urinary test. Treatments that reduce the exposure to paraquat by either reducing absorption or increasing clearance must be initiated promptly. In contrast, active treatment seems unlikely to be of assistance to patients in whom this test is strongly positive, or those with evolving multiorgan dysfunction. Instead, palliation should be the priority, including oxygen for hypoxia and morphine for dyspnea and oropharyngeal and abdominal pain.

Serial pulse oximetry measurements and chest radiographs will demonstrate development and progression of lung injury. Lung transplantation has been tried in patients with delayed respiratory failure, but it was largely unsuccessful because of the prolonged elimination half-life of paraquat.⁶ Patients developing acute kidney injury should receive hemodialysis or hemofiltration per usual guidelines if active treatment is to be pursued, and these treatments may also enhance elimination of herbicide if commenced promptly (see below).

Resuscitation and Supportive Care. All patients should receive prompt routine resuscitation and close observation. Oxygen should be administered to patients for palliation only when there is confirmed hypoxia and/or prognosis is extremely poor. Although controlled hypoxia does not prevent the development of pulmonary injury, unnecessary supplemental oxygen can theoretically hasten the progression of injury. Intravenous fluids should be administered to patients who are volume depleted from poor intake, diarrhea, or third-space shifts, as this may reduce the extent of acute kidney injury and promote renal clearance of paraquat. Care is required with volume resuscitation in the context of acute kidney injury to prevent fluid overload. Electrolyte abnormalities may also occur and these should be corrected as required.

Ongoing management includes regular clinical observations including urine output quantification, daily routine laboratory tests (or more frequently if clinically indicated) in patients receiving active treatment and supportive care. Analgesia for oral and abdominal pain should be administered as required, including intravenous opioids, such as morphine, and possibly topical anesthetics, such as lidocaine. Plain radiographs or a CT of the chest can provide information on lung and esophageal injury.

Gastrointestinal Decontamination. Paraquat is coformulated with an emetic so self-decontamination may have occurred by the time of presentation to hospital. Fuller's Earth and activated charcoal have been advocated to decrease absorption of paraquat. Both adsorb paraquat to a similar extent but Fuller's Earth is of limited supply.⁴ However, paraquat is rapidly absorbed so decontamination should be commenced within a few hours of ingestion. Gastric lavage has not been shown to improve outcomes and may even be harmful if administered to patients ingesting less than 30 mL.¹²⁷

Extracorporeal Removal. Extracorporeal techniques, including charcoal hemoperfusion, plasmapheresis, and hemodialysis/filtration, have been studied to decrease the systemic exposure by increasing the rate of elimination. Paraquat clearance by hemoperfusion is similar to endogenous clearance but exceeds it when there is impaired kidney function.^{53,67} Hemoperfusion is more efficient than hemodialysis, and clearance is maximized when treatment is initiated within the first couple of hours because the plasma concentration is high.³⁹ Further, given that paraquat rapidly distributes from the circulation, prompt treatment is necessary to limit the uptake into pulmonary and other tissues.⁸⁹

Experimentally, hemoperfusion reduces mortality in dogs only when it is commenced within a few hours of poisoning, and repeated treatments did not increase clearance to a large extent.⁸⁹ Other animal studies have suggested benefits from hemoperfusion when performed within one hour, including a decrease in paraquat exposure, less end-organ damage and a

reduction in inflammatory cytokines, but no mortality benefit.

Past experience suggested that extracorporeal treatments do not sufficiently improve mortality in humans, particularly when the concentration is greater than 3 mg/L.³⁵ Hemoperfusion followed by continuous venovenous hemofiltration may prolong the time to death compared with hemoperfusion alone without changing the overall mortality in a randomized, controlled trial. All patients in this study also received high-dose dexamethasone and ascorbic acid.⁵⁷ However, increasing publications from eastern Asia suggest a clinical benefit from these therapies if commenced early but confirmatory data would be of interest.

Extracorporeal techniques may also induce harm because of the requirement for central venous access, metabolic disequilibrium, or increased clearance of antidotes. Therefore, their use requires careful consideration on a case-by-case basis.

Antidotes. A large number of potential antidotes have been studied in the treatment of acute paraquat poisoning. They attempt to counteract the effects of paraquat by targeting various steps in the pathogenesis of organ dysfunction or to alter cellular uptake (Fig. 112–3). Unfortunately, none of these antidotes are proven to reduce mortality. Some of the interventions that decrease paraquat exposure by decreasing absorption¹²⁶ or increasing elimination⁵⁷ were shown to prolong the time to death. Therefore, combining these treatments with effective antidotes in a multimodal approach to treatment may reduce mortality. The combination (if any) that will improve outcomes is not known, more research is required to determine the role of the various proposed antidotes in routine clinical care.

Immunosuppression with corticosteroids (dexamethasone or methylprednisolone) and cyclophosphamide are the most extensively studied antidotes in humans. Early randomized controlled trial data (three trials, n = 164 patients) suggested a benefit from these treatments but due to limitations in study design these results were not considered conclusive.⁶⁸ This was followed by a larger randomized controlled trial (n = 298) that reported no mortality benefit from high dose immunosuppression (cyclophosphamide, methylprednisolone, dexamethasone) in patients with acute paraquat poisoning.²⁸ Therefore, this immunosuppressive regimen is not currently recommended.

Generation of reactive oxygen species is an important step in the pathogenesis of paraquat poisoning (Fig. 112–3). This leads to cytotoxicity, the extent of which depends on the concentration of paraquat at the cellular level and the efficiency of endogenous protective mechanisms. Scavenger defense mechanisms against reactive oxygen species include antioxidants such as vitamin C (ascorbic acid), vitamin E (α -tocopherol), and glutathione. Administration of these vitamins and/or a glutathione donor (eg, N-acetylcysteine, S-carboxymethylcysteine, captopril) to patients did not improve outcomes in every human or animal study. Poor intracellular penetration to the site of redox cycling may limit the effect of some compounds. Potentially, vitamin C might increase oxidative toxicity.²² Typical doses that have also been used in patients with acute poisoning include: vitamin E 300 mg orally twice daily, vitamin C 25 mg/kg/day or 3 g/day for 7 days, and N-acetylcysteine 150 mg/kg over 3 hours as a loading dose followed by 500 mg/kg/day by continuous infusion. The scavenging agents superoxide dismutase and amifostine and the iron chelator deferoxamine have also been studied, but results were not encouraging.

Some treatments may influence the toxicokinetics of paraquat at the cellular level. Xenobiotics that decrease the uptake of paraquat into pneumocytes have been studied such as putrescine, spermidine, and deferoxamine, but their effect is limited and they do not alter efflux. Corticosteroids, particularly dexamethasone and methylprednisolone, have been shown in animal models to induce p-glycoprotein, which increases the cellular efflux and excretion of paraquat.

Salicylates are proposed to inhibit multiple steps in the pathogenesis of paraquat poisoning, including decreasing production of reactive oxygen species, inhibition of NF- κ B, antithrombotic effects, and chelation of paraquat.^{20,21} Sodium salicylate 200 mg/kg decreased reactive oxygen species production and inflammation and improved survival in rats.²⁰ Similarly, lysine acetylsalicylate 200 mg/kg improved survival in rats in a dose-finding study.^{23,46} A small pilot study in Sri Lanka noted a delayed time to death in patients receiving intravenous acetylsalicylic acid. Other antidotes and treatments have also been proposed, but less information regarding their effects is available.

Treatment Recommendations. Most clinical studies have not demonstrated favorable outcomes, in contrast to animal studies, which may reflect higher toxicity or delayed institution of therapy. Studies reporting a delayed time to death suggest a possible effect, prompting further research into dose-response and the effect of combination therapy. Active treatment, particularly with invasive modalities such as hemoperfusion/dialysis is anticipated to interfere with end-of-life care. Based on these principles, our recommendations favor intervention where there may be a hope of recovery, while limiting therapeutics desperation. The prognosis in patients presenting more than 12 hours after ingesting 50 mL or more of paraquat 20% wt/vol, those with a positive plasma dithionite test, or those with a SIPP greater than 50 is so poor that treatment should focus on symptom control and end-of-life support and palliation. The prognosis in patients presenting within 6 hours of ingesting less than 50 mL of paraquat, those with a faint-positive dithionite test, or those with a SIPP less than 50 is also poor but prompt multimodal treatment with volume resuscitation, oral activated charcoal (or Fuller's earth), hemoperfusion or hemodialysis, intravenous corticosteroids, acetylsalicylate, acetylcysteine, deferoxamine, and vitamin E can be commenced. It cannot be over-emphasized that any potential benefit of these treatments is time-critical so they must be commenced immediately. If any of these treatments are not available at the initial treatment center it is reasonable to

transfer the patient to a center that can provide them within the stated timeframe. Other exposures not yet mentioned are associated with poor prognosis and unlikely to respond to treatment. However, if resources are available and psychosocial factors support aggressive treatment then the previous-mentioned treatment regimen can be attempted (but a benefit is not anticipated). In particular, it is not recommended that such patients be transferred to another center to receive active treatment

GLUFOSINATE

Glufosinate ($\{2RS\}$ -2-amino-4-{hydroxy(methyl)phosphinoyl}butyric acid; **Fig. 112–5**) is a nonselective herbicide used predominantly in Japan, which is where most cases of acute poisoning are reported; however, use is increasing in other parts of Asia. Commercial preparations contain 14% to 30% glufosinate as the ammonium or sodium salt, with anionic surfactants. Case fatalities between 6.1% and 17.7% are reported from glufosinate poisoning and increasing age is a risk factor.⁷⁴

FIGURE 112–5 Structure of glufosinate.

Pharmacology

Glufosinate is neurotoxic, although the specific mechanism is incompletely described. Because it is structurally similar to glutamate, studies have explored whether it interferes with glutamate networks in the central nervous system. Studies in rats demonstrate both agonism and antagonism to glutamate receptors and no effect on other receptors in the brain.³⁴ Glufosinate also interferes with glutamine synthetase activity, which can induce hyperammonemia. Ammonia concentrations were not markedly altered in rats,³⁴ but hyperammonemia has been observed following self-poisoning.^{34,60,73,124}

Glufosinate was not found to inhibit cholinesterase enzymes in rat studies,³⁴ although this is reported in humans on occasion, including one case where it decreased to 40% of the lower limit of normal with subsequent recovery.¹²⁴

The extent to which the surfactant contributes to clinical toxicity has not been confirmed. Rat studies suggest that hemodynamic changes due to glufosinate ammonium formulations are entirely caused by the surfactant component rather than glufosinate itself.⁵⁹ Surfactants may also cause uncoupling of oxidative phosphorylation, although this was not observed in a single case report of glufosinate ammonium poisoning.⁷⁰

Pharmacokinetics and Toxicokinetics

Kinetic analysis of glufosinate is limited to animal studies and a few human case reports. Minor differences in kinetics of the D- and L-glufosinate enantiomers are observed between patients, the clinical implications of which are not known.

The peak concentration is observed 1 hour postingestion in mice administered the formulated product, and less than 15% of a dose is absorbed by rats.

Glufosinate does not appear to bind to plasma proteins to a significant extent. The V_d was calculated to be 1.44 L/kg in a case of acute poisoning by assuming that the renal excretion of glufosinate is similar to animals.³⁸ Glufosinate distributes to the central nervous system, and in a case of acute poisoning the cerebrospinal fluid concentration was one-third the serum concentration 27 hours postingestion. The rate of distribution to the cerebrospinal fluid has not been characterized, but it is theorized that glufosinate might distribute to the central nervous system slowly (perhaps due to active transporters) where it accumulates, which is why the onset of respiratory depression is delayed.⁴⁴ This theory was not supported in a case where glufosinate was not detected in the cerebrospinal fluid 6 hours after a seizure that occurred 30 hours postingestion.¹²¹ Indeed, seizures have occurred in some patients after glufosinate was no longer detectable in the blood.¹²⁴ Seizures occur 3 hours postadministration of intracerebral glufosinate in rats, which further challenges the theory that distribution kinetics influence the delayed onset of seizures in humans.³⁴

Glufosinate is subject to minimal metabolism and the majority of the bioavailable dose of glufosinate is excreted unchanged in urine.

The elimination half-life is 4 hours in rats, while in rabbits elimination is biphasic with a terminal elimination half-life of 1.9 hours, which is not dose dependent. Kinetic data in humans are limited to a small number of cases of acute

intentional poisoning where the elimination profile appeared biphasic with a distribution half-life of 2 to 4 hours and a terminal elimination of 10 to 18 hours.^{38,41,118}

Pathophysiology

It is not known whether the manifestations of glufosinate poisoning represent a primary (toxic) or secondary (downstream) effect. The most important manifestations are neurological, with respiratory impairment that reduces oxygen delivery and subsequently compromises cellular function. Hypotension also impairs tissue perfusion and if uncorrected progresses to shock. Failure to correct these abnormalities may lead to irreversible cellular injury and death.

Clinical Manifestations

Nausea and vomiting are early features of acute poisoning. An altered level of consciousness precedes severe neurotoxicity, which occurs between 4 and 50 hours postingestion, and includes seizures and central respiratory failure requiring ventilatory support.^{60,73,74} These symptoms may persist for a number of days. In rats, the onset of seizures is also delayed by a number of hours; however, the time to onset of the seizures decreased in a dose-dependent manner following the intraperitoneal administration of glufosinate.⁷⁵

Other manifestations include cardiac dysrhythmias, fever, amnesia (antegrade and retrograde), diabetes insipidus, and rhabdomyolysis. Refractory hypotension may be preterminal.^{60,73,74}

Diagnostic Testing

Glufosinate poisoning is diagnosed clinically in the context of a history of exposure. Glufosinate assays are available for clinical use in Japan and a nomogram was developed for predicting clinical outcomes (Fig. 112–6).⁴⁰ Clinical chemistry assays including kidney function, blood gases, electrolytes, creatine kinase, and ammonia concentrations may support clinical management. Metabolic acidosis is more common with severe poisoning.⁷⁴ The ammonia concentration is not often markedly elevated or does not consistently correlate with clinical outcomes. If serial measurements identify an increasing concentration this may suggest increased risk of neurotoxicity.^{34,60,73}

FIGURE 112–6 Glufosinate nomogram as described by Hori et al.⁴⁰ Concentrations above the line are associated with more severe poisoning.

Management

Although toxicity appears to be dose dependent, severe symptoms are reported following unintentional ingestion, so all patients with oral exposures should be carefully monitored. Patients with confirmed exposures should be monitored for a minimum of 48 hours because the onset of clinical toxicity can be delayed. Prior to discharge, each patient should be carefully screened to identify those with memory deficits.

Resuscitation and Supportive Care. Routine resuscitation, close observation, and supportive care are required. Careful monitoring for the onset of respiratory failure is necessary and early intubation and ventilation is recommended in symptomatic patients. Given that glufosinate and metabolites are primarily renally cleared, intravenous fluids to maintain a consistent urine output is suggested. Seizures should be treated in a standard manner initially with benzodiazepines as first-line therapy. This approach is suggested to be effective on the basis of animal studies. Biochemical and acid–base abnormalities should be corrected where possible.

Gastrointestinal Decontamination. In most reports of glufosinate poisoning, gastric lavage and activated charcoal were administered, but it is not possible to determine whether these interventions improved clinical outcomes. The high incidence of both seizures and respiratory failure from glufosinate poisoning are relative contraindications to the administration of activated charcoal to patients with an unprotected airway.

Extracorporeal Removal. Hemodialysis and hemoperfusion have been used in the management of acute glufosinate poisoning. Hemodialysis appears to be superior to hemoperfusion in terms of extraction of glufosinate from whole blood in vitro, with an extraction ratio of 80%. However, the clearance by hemodialysis is less than 60% of renal clearance in patients with normal kidney function. Prompt hemodialysis in patients decreases the concentration of glufosinate and probably ammonia but it is not known if this prevents the occurrence of neurotoxicity such as seizures, so its role in routine management is poorly defined. It is reasonable to consider these treatments in patients with severe poisoning and also in those with impaired kidney function.

Antidotes. Specific antidotes are not available. Rat studies did not demonstrate benefit with the use of atropine and pralidoxime. Ethanol coingestion appears to be protective. Benzodiazepines should be first-line therapy for seizures.

GLYPHOSATE

Glyphosate (N-{phosphonomethyl} glycine; Fig. 112–7) is a nonselective postemergence herbicide. It is used extensively worldwide, most commonly as the isopropylamine salt but also a potassium salt. Glyphosate-containing herbicides are available in various formulations: 1% to 5% glyphosate (ready to use) or 30% to 50% (concentrate requiring dilution before use). In 2007, glyphosate was the most frequently used herbicide in the United States and the second most commonly used herbicide in the domestic sector.³³ Products containing glyphosate trimesium are less widely used and may differ with respect to their toxicity profile.

FIGURE 112–7 Structure of glyphosate.

Pharmacology

Glyphosate inhibits 5-enolpyruvylshikimate-3-phosphate synthase in plants, which interferes with their aromatic amino acid synthesis; this enzyme is not present in humans.

The mechanism of toxicity of glyphosate-containing herbicides to humans is not adequately described. The formulation is irritating and high concentrations are corrosive, causing direct injury to the gastrointestinal tract. Despite being an organic phosphorus compound, glyphosate does not inhibit acetylcholinesterase. Patients with severe poisoning manifest multisystem effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiologic process common to a number of systems. Proposed mechanisms include disruption of cellular membranes and uncoupling of oxidative phosphorylation, which may be interrelated. Indeed, the mechanism of toxicity may vary between different glyphosate salts. In two cases of glyphosate trimesium poisoning, cardiopulmonary arrest occurred within minutes of ingestion.^{81,116} Since this is not reported from glyphosate isopropylamine, it is possible that these products differ in the mechanism of toxicity.

Experimentally, there is minimal (if any) mammalian toxicity from glyphosate itself. Glyphosate is categorized as WHO class “U” (unlikely to present acute hazard in normal use; LD₅₀ > 4000 mg/kg).⁴⁹ Surfactant coformulants are considered the more toxic component in glyphosate-containing herbicides. Polyoxyethyleneamine (tallow amine; LD₅₀ equal to 1200 mg/kg) is the most common surfactant formulated in these products, but others are also used. Systemic exposure to surfactants induces hypotension, which is primarily due to direct effects on the heart and blood vessels.¹³ Surfactants directly disrupt cellular and subcellular membranes, including those of mitochondria, which has the potential to lead to systemic symptoms.³² Coformulated potassium and isopropylamine may also contribute to toxicity. Isopropylamine has a rat LD₅₀ of 111 to 820 mg/kg, decreases vascular resistance, and may either increase or decrease cardiac contractility and rate.^{50,93}

Pharmacokinetics and Toxicokinetics

The kinetics of the surfactant has not been described. The relevance of the kinetics of glyphosate is questioned because its

contribution to clinical toxicology is minimal; however, it is summarized here for completeness. Glyphosate does not penetrate the skin to a significant extent. Up to 40% of an oral dose is absorbed in rats, although this could increase when ingested as a concentrated solution with injury to the gastrointestinal epithelium. The peak glyphosate plasma concentration occurs within 2 hours of ingestion and distribution appears to be limited (glyphosate does not readily cross the placenta according to an ex vivo model⁸²). Glyphosate has an elimination half-life that is less than 4 hours and is excreted unchanged in the urine.^{7,9,43,100,125}

Pathophysiology

It is not known whether the manifestations of glyphosate poisoning represent a primary (toxic) or secondary (downstream) effect. Disruptions of oxidative phosphorylation globally impair normal cellular function as a result of limited energy supply (discussed further with the pathophysiology of phenoxy herbicides). Similarly, direct toxicity to cell membranes (including those of the mitochondria) interferes with normal cellular processes such as ion channels. Both disruptions induce multiorgan toxicity. Hypotension and dysrhythmias impair tissue perfusion, and liver and kidney injuries induce metabolic disequilibria and acidosis, which impair normal physiologic processes. Pulmonary toxicity may lead to hypoxia, which further compromises normal cellular functioning. Failure to correct these abnormalities may lead to irreversible cellular toxicity and death.

Clinical Manifestations

Abdominal pain with nausea, vomiting, and/or diarrhea are the most common manifestations of acute poisoning. These may be mild and self-resolving, but in patients with severe poisoning there may be inflammation, ulceration, or infarction. Severe diarrhea and recurrent vomiting may induce dehydration. Gastrointestinal burns and necrosis occur with high doses of concentrated formulations and may be associated with hemorrhage. Extensive erosion of the upper gastrointestinal tract is associated with more severe systemic poisoning and a prolonged hospitalization.^{14,15,47,79,100}

Severe poisoning manifests as multiorgan failure, including hypotension, cardiac dysrhythmias, kidney and liver dysfunction, hyperkalemia, pancreatitis, pulmonary edema or pneumonitis, altered level of consciousness including encephalopathy, and metabolic acidosis. These effects may be transient or severe, progressing over 12 to 72 hours to resistant shock, respiratory failure, and death. The mechanism of hypotension may relate to both hypovolemia (fluids shifts and increased losses) and/or direct cardiotoxicity.^{7,15,65,69,79,100,111,120}

Intravenous self-administration of glyphosate-containing herbicide caused hemolysis in one patient, and intramuscular self-administration caused rhabdomyolysis in another.

A large prospective study reported a case fatality of 3.2% in patients presenting to rural hospitals in Asia where resources are limited,¹⁰⁰ but mortality reported in other studies varied from 2% to 30%.¹⁵ These differences in outcomes may reflect differences in timely access to health care services, available medical facilities, variability in glyphosate formulations, or selection bias related to case-referral. Proposed risk factors for death include a large exposure, delayed presentation to hospital, elevated glyphosate concentration, and increasing age.^{15,79,100,111}

Respiratory, ocular, and dermal symptoms may occur following occupational use of these preparations but are usually of minor severity. Significant skin reactions from topical exposure are also reported.

Diagnostic Testing

Acute poisoning with a glyphosate-containing herbicide is diagnosed on the basis of a history of exposure and clinical findings. The differential diagnoses are wide, including any xenobiotic or medical condition associated with gastrointestinal effects and progressive multisystem toxicity.

A number of clinical criteria for the classification of severity are suggested, but none have been validated.^{7,100,120,122} There are no readily available specific clinical investigations to guide management or estimate prognosis in acute poisoning. Higher glyphosate plasma concentrations are associated with more severe poisoning; for example concentrations greater than 734 mg/L predicted death in one study,¹⁰⁰ while a review noted that severe poisoning is associated with concentrations greater than 1000 mg/L.⁷ These concentrations probably reflect the amount of exposure, since glyphosate is minimally toxic. However, quantitative glyphosate assays are not routinely available for clinical use.

Targeted laboratory and radiological investigations should be conducted in patients demonstrating anything more than mild gastrointestinal symptoms. Pulse oximetry and blood gas measurements may be useful for detection of metabolic disequilibria and respiratory impairment. Electrolytes should be measured early because some formulations contain glyphosate as a potassium salt and severe hyperkalemia is reported.

Patients who develop marked nonspecific organ toxicity (eg, acute kidney injury, pulmonary edema, metabolic acidosis, sedation, dysrhythmias, hypotension) are more likely to die.^{15,62,64,79,100}

Endoscopy can diagnose erosions or ulceration following exposures to the concentrated formulation. However, this

procedure may be complicated by perforation and may not change management, so its use requires careful consideration.

Management

Retrospective studies suggest a correlation between ingestion, severity of poisoning, and death.^{64,100,106,122} All patients except for those with trivial exposures should be observed for a minimum of 6 hours. In particular, patients presenting with intentional self-poisoning or ingestion of a concentrated formulation must be carefully monitored. If gastrointestinal symptoms are noted then the patient should be observed for a minimum of 24 hours given that clinical toxicity may progress. Because the toxicity of individual surfactants has not been determined, treatment does not vary depending on specific coformulants.

Resuscitation and Supportive Care. All patients should receive prompt resuscitation, close observation, and routine supportive care; other treatments are largely empiric. The airway is usually maintained but respiratory failure and respiratory distress occur, which require supplemental oxygen and possibly mechanical ventilation. The optimal management of hypotension is complicated because its etiology is potentially related to hypovolemia, negative inotropy, and/or reduced vascular resistance. A detailed clinical review is required, followed by cautious administration of intravenous fluids to the patient. If the response to prompt administration of 20 to 30 mL/kg intravenous fluid to the patient is insufficient or there is increasing pulmonary congestion, then vasopressors should be used. Other investigations such as echocardiography, central venous pressure, or pulmonary artery catheter may also guide management, if available.

Biochemical and acid–base abnormalities, such as hyperkalemia, should be corrected where possible. The contribution of uncoupling of oxidative phosphorylation to clinical toxicity and death has been proposed, but no specific treatment is available if this develops. In the context of acute poisoning with glyphosate-containing herbicides, signs suggestive of uncoupling of oxidative phosphorylation, such as hyperthermia, metabolic acidosis with elevated lactate concentration, and hypoglycemia, may be a preterminal event. Hemodialysis or hemofiltration should be administered to patients developing acute kidney injury per usual guidelines if active treatment is to be pursued.

Gastrointestinal Decontamination. No data exist to support the role of gastrointestinal decontamination in acute poisoning with glyphosate-containing herbicides beyond the usual recommendations discussed above.

Extracorporeal Removal. Patients who received hemodialysis have survived severe poisoning; however, other patients have died despite this treatment. Plasmapheresis has also been studied but clearances were not determined. Early initiation of any of these treatments may be required for best results. The role of extracorporeal removal in routine care is not known given that there are limited quantitative data reporting direct clearances, and uncertainty regarding what compound to measure.

Antidotes. No specific antidote has been proposed or tested for the treatment of acute poisoning with glyphosate-containing herbicides, which relates in part to the unknown mechanism of toxicity.

PHENOXY HERBICIDES (PHENOXYACETIC DERIVATIVES), INCLUDING 2,4-D AND MCPA

Phenoxy compounds are selective herbicides that are widely used in both developing and developed countries. A large number of compounds are included in this category; however, the most widely used are the phenoxyacetic derivatives. This includes 2,4-dichlorophenoxyacetic acid (2,4-D), MCPA, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T; no longer available), and mecoprop (MCP; 2-(4-chloro-2-methylphenoxy)propionic acid; Fig. 112–8). Other phenoxy herbicides and available toxicity data are listed in Table 112–1. In 2007, 2,4-D was the fifth most commonly used herbicide in the United States but the most commonly used herbicide in the domestic sector (MCP was fourth most commonly used in the domestic sector).³³

FIGURE 112–8 Structures of common phenoxy herbicides.

Agent Orange, a defoliant popularly used during the Vietnam War, was composed of an equal mixture of 2,4-D and 2,4,5-T. This product also contained the contaminant dioxin (2,3,7,8-tetrachlorodibenzodioxin), which was a byproduct of

the manufacture of phenoxy herbicides. Dioxin is a persistent organic pollutant that is alleged to induce chronic health conditions and cancer, although this has been debated. This chapter discusses only the outcomes of acute exposures to phenoxy herbicides.

Pharmacology

The mechanism of toxicity of phenoxy compounds is not well described. The formulation is irritating or corrosive, causing direct injury to the gastrointestinal tract. Patients with severe poisoning manifest multisystem effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiological process common to a number of systems. As with other herbicide preparations, this may reflect the contribution of coformulants such as surfactants.

In rats, high plasma concentrations of MCPA damage cell membranes and induce toxicity, but the correlation between plasma concentrations, membrane damage, and toxicity is poor. Dose-dependent kidney injury from 2,4-D is observed in rats.

Uncoupling of oxidative phosphorylation also may contribute to the development of severe clinical toxicity. Phenoxyacetic derivatives demonstrate concentration-dependent uncoupling of rat mitochondria in vitro, although the specific process that is disrupted is not sufficiently described.^{10,133} Features of uncoupling of oxidative phosphorylation were observed antemortem in clinical studies of patients with large phenoxy herbicide exposures.⁹⁸

Phenoxy acid compounds inhibit the voltage-gated chloride channel CLC-1 in skeletal muscles, which is thought to contribute to the neuromuscular toxicity of these compounds. Dysfunction of CLC-1 induces myotonia due to hyperpolarization of the cell membrane. Other CLC channels are important for normal renal physiology. There are differences in the degree of inhibition between individual phenoxy acid compounds, which may contribute to the variability in animal LD₅₀ and possibly clinical features.

Other possible mechanisms of toxicity relate to their similarity to acetic acid, interfering with the utilization of acetylcoenzyme A (acetyl-CoA), or action as a false messenger at cholinergic receptors.⁸

Pharmacokinetics and Toxicokinetics

Animal studies and human case reports have shown nonlinear kinetics for the phenoxy herbicide compounds. Dose-dependent changes in absorption, protein binding, and clearance all occur, and each will influence the concentration-time profile.

Absorption is usually first order¹; however, the time to peak concentration may be delayed with increasing doses, which may suggest saturable absorption (this is supported by cell culture studies that demonstrate active absorption of these herbicides by a hydrogen ion-linked monocarboxylic acid transporter).^{55,61,101,123}

As the dose of MCPA increases there is a change in the semilogarithmic plasma concentration-time profile from linear to a biphasic convex profile. The inflection of this elimination curve in rats is approximately 200 mg/L,^{25,26,101,123} which appears to reflect saturation of albumin binding. As the plasma concentration exceeds this point the proportion of herbicide that is free (unbound) increases.¹⁰¹ This may increase the Vd and prolong the apparent plasma elimination half-life.

Another contributing mechanism to the observed biphasic convex concentration-time profile is saturation of renal clearance for which there is some interspecies variability. Dose-dependent renal clearance is attributed to saturation of an active transport process or direct nephrotoxicity. Renal clearance also varies with urine flow because of reabsorption from the distal tubule.

Similar to data from animal studies, the semilogarithmic plasma concentration-time curve of phenoxy herbicides in humans with acute poisoning is generally convex, with an apparent inflection from a longer (but highly variable) to shorter elimination half-life between 200 and 300 mg/L. The elimination half-lives are prolonged, which may explain the persistence of clinical toxicity and why death may occur a number of days postingestion of a phenoxyacetic herbicide.^{98,101}

Alterations in blood pH may also change tissue distribution because phenoxyacetic herbicides are weak acids (pKa ~ 3). Here, acidemia increases the proportion that is nonionized, and therefore lipophilic, which increases tissue binding and distribution. This has been observed in vitro and is similar to that observed for salicylates (Chap. 39). Similarly, an alkaline plasma pH is expected to decrease tissue (and probably receptor) binding and increase plasma concentrations.

Experience with acute human poisonings noted a poor correlation between plasma concentrations and peak toxicity.⁹⁸ This may reflect a discordance between plasma (measured) and intracellular (eg, mitochondrial) concentrations.

Pathophysiology

Direct injury to the gastrointestinal tract may cause vomiting and diarrhea, which induces hypovolemia and electrolyte abnormalities.⁸ Nonspecific cellular toxicity and uncoupling of oxidative phosphorylation interfere with normal function of ion channels and other cellular functions, preventing normal physiological processes.

Uncoupling of oxidative phosphorylation may be caused by chemicals that disrupt mitochondrial function, and causes

inefficiency in energy production. At a cellular level it describes an increase in oxygen consumption and heat production out of proportion to the generation of ATP due to mitochondrial dysfunction. Varying degrees of uncoupling of oxidative phosphorylation may occur. The initial physiological response to uncoupling is to increase mitochondrial respiration to maintain the supply of ATP, which increases heat production and respiratory rate. As ATP falls there is an increase in glycolysis, causing hypoglycemia and metabolic acidosis with an elevated lactic concentration. If the mitochondrial defect persists then there will be hyperthermia and insufficient ATP for essential cellular functions including active transport pumps such as $\text{Na}^+\text{-K}^+\text{-ATPase}$. This is followed by a loss of cellular ionic and volume regulation, which, if persistent, is irreversible and cell death occurs. Because mitochondria are the primary supplier of ATP for most physiologic systems, uncoupling of oxidative phosphorylation is expected to induce multisystem toxicity.

Clinical Manifestations

Vomiting, myotonia (confirmed on electromyography), and miosis are prominent features of 2,4-D poisoning in dogs. Severity varies in a dose-dependent manner, peaking 12 to 24 hours postingestion and persisting for a number of days.

Gastrointestinal toxicity including nausea, vomiting, abdominal or throat pain, and diarrhea are common. Other clinical features include neuromuscular findings (myalgia, rhabdomyolysis, weakness, myopathy, myotonia, and fasciculations), central nervous system effects (agitation, sedation, confusion, miosis), tachycardia, hypotension, kidney toxicity, and hypocalcemia. In some patients, these effects persist for a number of days.⁹⁸

Tachypnea with respiratory alkalosis occurs in patients with phenoxy herbicide poisoning, some of who died, which may be consistent with increased mitochondrial respiration from mild uncoupling. More severe poisoning may be characterized by metabolic acidosis, hyperventilation, hyperthermia, elevated creatine kinase, generalized muscle rigidity, progressive hypotension, pulseless electrical activity, or asystole.^{8,19,85,98}

The mortality from acute phenoxy herbicide poisoning is potentially high. A systematic review of all acute phenoxy herbicide poisoning described severe clinical toxicity in most patients, including death in one-third of the cases.⁸ Subsequently, a prospective study of MCPA exposures in Sri Lanka demonstrated minor toxicity in greater than 80% of patients and a mortality of 4.4% (eight of 181 patients).⁹⁸ When death occurs, it is usually delayed by 24 to 48 hours postingestion and results from cardiorespiratory arrest. The exact mechanism of death is inadequately described, but it may relate to uncoupling of oxidative phosphorylation or other metabolic dysfunction including acute kidney injury, as discussed above.

Diagnostic Testing

Commercial assays for the specific measurement of phenoxy herbicides are not available to assist in the diagnosis of acute poisoning. Further, their role in the management of acute poisoning is not confirmed because the relationship between plasma phenoxy herbicide concentration and clinical toxicity appears to be poor.⁹⁸ Sedation is reported with a plasma phenoxy concentration above 80 mg/L,⁹⁶ while concentrations more than 500 mg/L are associated with severe toxicity.²⁷ A patient survived severe MCPA poisoning (hypotension and limb myotonia) with a plasma concentration of 546 mg/L. The myotonia persisted for a number of days and resolved when the MCPA plasma concentration was less than 100 mg/L.¹⁰⁹ By contrast, death has been reported following MCPA poisoning at plasma concentrations as low as 107 mg/L to 230 mg/L.^{51,90,98}

Monitoring of electrolytes, kidney function, pulse oximetry, and blood gases is recommended to detect progression of organ toxicity. Hypoalbuminemia may predispose to severe poisoning.¹⁰¹ Creatine kinase should be determined since rhabdomyolysis may occur following acute poisoning. Urinalysis might be useful for identifying myoglobinuria. There are insufficient data describing the role of these measurements for prognostication.

Management

All patients with significant poisonings, particularly those with symptomatic oral ingestions, should be treated cautiously, including continuous monitoring for 24 to 48 hours preferably in an intensive care unit. Initial mild toxicity (eg, gastrointestinal symptoms but normal vital signs and level of consciousness at presentation) does not preclude subsequent severe toxicity and death.⁹⁸

Animal studies suggest that phenoxy herbicide toxicity increases when elimination is impaired. Empirically, this supports the use of treatments that reduce exposure by either decreasing absorption or increasing elimination. Unfortunately, there is insufficient evidence to recommend specific interventions in patients with acute phenoxy herbicide poisoning. However, an adequate urine output ($> 1 \text{ mL/kg/h}$) may optimize the renal excretion of phenoxy herbicides as well as decreasing renal toxicity from rhabdomyolysis. Since signs consistent with uncoupling of oxidative phosphorylation are likely to be associated with a poor outcome, more advanced treatments such as hemodialysis can be considered in these patients.^{8,98}

Resuscitation and Supportive Care. All patients should receive routine resuscitation, close observation, and supportive care. It is reasonable to correct electrolyte abnormalities and acidemia given that this may promote the distribution of weak acids and increase the intracellular concentration.

Gastrointestinal Decontamination. Gastrointestinal decontamination can be administered to patients per the guidelines listed in [Chap. 8](#). However, administration of activated charcoal beyond the usual time frame is reasonable given that absorption appears to be saturable.

Extracorporeal Removal. Because phenoxy compounds are small and water soluble, and subject to saturable protein binding with large exposures (increasing the free concentration), they are likely to be cleared by extracorporeal techniques. Extracorporeal elimination using resin hemoperfusion, hemodialysis, or plasmapheresis has been studied in a few cases, with clearances approaching 75 mL/minute. Hemodialysis should be considered in patients with severe poisoning if facilities are available.

Antidotes. There are no specific antidotes for phenoxy herbicides, but sodium bicarbonate or other alkalinizing agents may have a role in management by altering the kinetics of phenoxy herbicides.

Data from animal studies and case reports suggest that urinary alkalization increases the elimination of phenoxy herbicides. Increases in urinary pH increase clearance due to “ion trapping” of the phenoxy herbicide. For example, renal 2,4-D clearance was increased from 5.1 mL/minute to 63 mL/minute when urine pH increased from 5.0 to 8.0.⁹¹ Compared with a total clearance of approximately 30 mL/minute or less in volunteer studies,^{56,105} this increase in renal clearance has the potential to be clinically significant. Prospective, randomized studies are required to confirm the efficacy of urinary alkalization in humans.

Plasma alkalization may also limit the distribution of phenoxy compounds from the central circulation by “ion trapping.”

It is reasonable to consider plasma and urinary (urine pH > 7.5) alkalization in patients who are symptomatic, particularly if there are features of uncoupling of oxidative phosphorylation or metabolic acidosis. Alkalization is rarely associated with adverse effects when administered to patients with care and close observation (Antidotes in Depth: A5).

TRIAZINE COMPOUNDS, INCLUDING ATRAZINE

The 1,3,5-triazine or s-triazine compound ([Fig. 112–9](#)) is central to a large number of compounds, including herbicides, other pesticides (eg, cyromazine), resins (eg, melamine), explosives (RDX or C-4), and anti-infectives. Triazine herbicides are widely used, and in 2007 atrazine and simazine were among the 25 most used pesticides in the United States.³³ However, cases of acute poisoning are infrequent. Other herbicides included in this group are listed in [Table 112–1](#). These selective herbicides may be used pre- or postemergence for weed control.

FIGURE 112–9 Structures of common triazine herbicides.

The safety of atrazine from an environmental health perspective is debated because of its persistence and propensity to spread across water systems and potential toxicity from chronic exposure. This led to restrictions on the use of triazine compounds in the European Union.

Pharmacology

The mechanism of toxicity is not fully determined, although it might relate to uncoupling of oxidative phosphorylation. Atrazine is a direct arteriolar vasodilator. Some metabolites of atrazine, particularly those remaining chlorinated, are thought to retain some biologic activity.² Similarly, clinical features of prometryn poisoning resolved posthemodialysis despite persistence of the parent herbicide, suggesting that toxic metabolites were eliminated.¹¹

Pharmacokinetics and Toxicokinetics

Approximately 60% of an oral atrazine dose is absorbed in rats and the concentration peaks beyond 3 hours.⁷⁸ The absorption phase of triazine compounds appears to be prolonged in humans where the serum or plasma concentration

continues to increase during treatment with hemodialysis.^{11,88} Atrazine is rapidly dealkylated to a metabolite that binds strongly to hemoglobin and plasma proteins, allowing it to be detected in the blood for months. Metabolites are excreted in the urine and around 25% of them are conjugated to glutathione.⁷⁸

The metabolism of atrazine has been studied in humans following occupational exposures, and animals, and a range of metabolites are described, in particular those derived from glutathione conjugation. Other metabolic products as a result of dealkylation and oxidation are also present.

Dermal absorption of atrazine is incomplete but increases with exposure to the proprietary formulation. Atrazine metabolites are readily measured in the urine of atrazine applicators.

Clinical Manifestations

There are limited cases of triazine herbicide poisoning. Vomiting, depressed level of consciousness, tachycardia, hypertension, acute kidney injury, and metabolic acidosis with elevated lactate concentration were described in a patient with acute prometryn and ethanol poisoning.¹¹ Similar clinical signs, in addition to hypotension with a low peripheral vascular resistance, were noted in a case of poisoning with atrazine, amitrole (Table 112–1), and other toxic compounds. This was followed by progressive multiorgan dysfunction and death due to refractory shock 3 days later.⁸⁸ Death following acute ametryn poisoning (coformulated with xylene and cyclohexanone) is reported, but the mechanism of death was not apparent.¹¹⁹

Diagnostic Testing

In a single case report, clinical toxicity did not directly relate to the concentration of prometryn, but the relationship to the concentration of metabolites has not been determined.¹¹ Routine biochemistry and blood gases are useful for monitoring for the development of systemic toxicity.

Management

Few publications of triazine herbicide poisoning are available to guide management of patients with acute triazine poisoning.

Resuscitation and Supportive Care. Routine resuscitation, close observation, and supportive care should be provided to all patients. Ventilatory support and correction of hypotension and metabolic disequilibria are reasonable.

Gastrointestinal Decontamination. It is reasonable to administer activated charcoal to patients beyond one hour because of the slow absorption of these compounds.

Extracorporeal Removal. Hemodialysis corrected metabolic acidosis in a case of prometryn poisoning without decreasing the serum concentration of prometryn, which might reflect ongoing absorption. In the absence of direct measurements of clearance, the efficacy of hemodialysis in removing prometryn cannot be determined, but is probably limited.¹¹ Hemodialysis clearance of atrazine was 250 mL/minute (extraction ratio 76%), but only 0.1% of the dose was removed after 4 hours of treatment. Further, similar to the previous case, atrazine concentrations continued to increase during the treatment.⁸⁸

Antidotes. No antidotes are available for the treatment of triazine herbicide poisoning.

SUMMARY

- A large number of heterogeneous xenobiotics are classified as herbicides; the toxicity in humans is not completely described for many of these xenobiotics.
- Coformulants, such as surfactants and solvents, probably contribute to clinical toxicity in commercial preparations.
- Many herbicides induce multisystem toxicity for which treatments are often unsatisfactory, although some compounds induce organ specific toxicity.
- All patients with acute intentional poisoning should be carefully observed for the development of poisoning.
- The priorities of treatment include prompt resuscitation, consideration of antidotes, a detailed history, ongoing monitoring, and supportive care.
- More research is required to better define the clinical syndromes associated with herbicide poisoning, the toxicokinetics of relevant compounds, and the efficacy of treatments including antidotes.

113 INSECTICIDES: ORGANIC PHOSPHORUS COMPOUNDS AND CARBAMATES

Michael Eddleston

HISTORY AND EPIDEMIOLOGY

The first potent synthetic organic phosphorus anticholinesterase, tetraethylpyrophosphate (TEPP), was synthesized by Clermont in 1854. Clermont's report described the taste of the compound, a remarkable achievement because a few drops should be rapidly fatal.¹¹¹ In 1932, Lange and Krueger wrote of choking and blurred vision following inhalation of dimethyl and diethyl phosphorofluoridates. This account inspired Schrader in Germany to begin investigating these agents, initially as pesticides, and later for use in warfare (Chap. 132). During this research, Schrader's group synthesized hundreds of compounds, including the popular pesticide parathion and the chemical weapons sarin, soman, and tabun. Allied scientists were also motivated during the same period by the work and independently discovered other extremely toxic compounds such as diisopropylphosphofluoridate (DFP).²¹⁴ Since that time, it is estimated that more than 50,000 organic phosphorus compounds have been synthesized and screened for pesticidal activity, with dozens being produced commercially.⁴⁰

The history of carbamates was first recorded by Westerners in the 19th century when they observed that the Calabar bean (*Physostigma venenosum* Balfour) was used in tribal cultural practice in West Africa.¹¹² These beans were imported to Great Britain in 1840, and in 1864 Jobst and Hesse isolated an active alkaloid component they named "physostigmine." Vée and Leven (1865) claimed to have obtained physostigmine in crystallized form and named it eserine, from *ésère*, the African term for the ordeal bean. Physostigmine was first used medicinally to treat glaucoma in 1877.¹¹² In the 1930s, the synthesis of aliphatic esters of carbamic acid led to the development and introduction of carbamate pesticides, marketed initially as fungicides. In 1953, the Union Carbide Corporation developed and marketed carbaryl, the insecticide being prepared at the plant in Bhopal, India, during the catastrophic release of methyl isocyanate in 1984 (Chap. 2).^{8,193}

Organic phosphorus compounds (OPs) and carbamates are the two groups of cholinesterase-inhibiting pesticides that commonly produce human toxicity. Although the term organophosphate is often used in both clinical practice and in the literature to refer to all phosphorus-containing pesticides that inhibit cholinesterase, phosphates are compounds in which the P atom is surrounded by four O atoms, and there are other derivatives of phosphoric and phosphonic acids such as phosphonates that can exhibit cholinesterase inhibition. Some chemicals, such as parathion, contain thioesters, whereas others are vinyl esters. Those cholinesterase-inhibiting (anticholinesterase) insecticides that contain phosphorus will be collectively termed organic phosphorus compounds in this chapter. Those that contain the OC=ON linkage will be termed carbamates.

Anticholinesterase pesticides are broadly grouped according to their toxicity by the World Health Organization's Classification of Pesticides into five groups: Class Ia "Extremely hazardous," Class Ib "Highly hazardous," Class II "Moderately hazardous," Class III "Slightly hazardous," and "Active ingredients unlikely to present acute hazard in normal use" (Table 113–1). This classification is based upon comparative rat oral LD₅₀ data of the active ingredient. It seems useful to distinguish very toxic OPs (such as parathion, rat oral LD₅₀ 13 mg/kg) that have killed many thousands of people from relatively safe OPs (such as temephos, rat oral LD₅₀ 8600 mg/kg) that have not been reported to cause harm. However, the rat LD₅₀ seems to be less useful to distinguish between pesticides within the same class. Here, the differential toxicity may be due to differences in response to treatment, speed of onset, or coformulants.^{51,69}

TABLE 113–1. WHO Classification of Pesticide Toxicity²³⁶

		<i>LD₅₀ for the Rat (mg/kg body weight)</i>			
		<i>Oral</i>		<i>Dermal</i>	
	<i>Class</i>	<i>Solids</i>	<i>Liquids</i>	<i>Solids</i>	<i>Liquids</i>
Ia	Extremely hazardous	5 or less	20 or less	10 or less	40 or less
Ib	Highly hazardous	5–50	20–200	10–100	40–400
II	Moderately hazardous	50–500	200–2000	100–1000	400–4000
III	Slightly hazardous	Over 500	Over 2000	Over 1000	Over 4000

Reproduced with permission of World Health Organization. The WHO recommended classification of pesticides by hazard and guidelines to classification: 2009. Geneva: WHO; 2010.

Globally, anticholinesterase insecticides likely kill more people each year than acute poisoning by any other chemical. An estimated 200,000 die in rural Asia where intentional self-harm is common and extremely toxic organophosphorus insecticides are widely used in agriculture and therefore available in households at times of stress.^{62,99} Around 3000 to 6000 ventilators are constantly required in Asia alone to provide mechanical ventilation to poisoned patients.⁹⁹ Banning of the most toxic organic phosphorus insecticides has resulted in a 50% fall in total suicides in Sri Lanka, showing that regulation can be effective.¹⁰⁰ Severe occupational or unintentional poisoning also happens where such insecticides are used,²²⁷ but deaths are generally less common.

Anticholinesterase poisoning is less important in industrialized countries where access to toxic pesticides is much more controlled. However, when anticholinesterase poisoning does occur, patients often require intensive care with long hospital stays.^{79,180} A further threat is the terrorist use of organic phosphorus insecticides, such as parathion, to poison a water supply or flour used in bread baking. Such events occur regularly in rural India^{57,164} and might result in many hundreds of casualties being treated by clinicians with little experience of this potentially lethal toxic syndrome.

The case fatality for OP and carbamate poisoning will vary according to which pesticides are used in local agriculture and the health facilities available. Where fast acting, highly toxic pesticides are used in agriculture and therefore for self-harm (as in much of the rural developing world), deaths will occur before patients present to hospital. Hospital based data therefore has a falsely low case fatality, although often still high at 10% to 30%.⁶²

Before the ban of parathion in Germany, the case fatality in Munich's toxicology intensive care unit was approximately 40%.^{79,240} This was likely because the excellent ambulance services in Germany were able to get to patients early, before death, but after they had become symptomatic with this fast acting OP. Some had already aspirated or suffered hypoxic brain injury prior to arrival of the ambulance. Despite resuscitation at the scene, many of these patients died subsequently from complications of the pre-hospital events rather than from direct cholinergic effects of the OP insecticide. Few of these patients would have survived to hospital admission in the developing world.

During the 5-year period of 2002 through 2006, the American Association of Poison Control Centers (AAPCC) recorded almost 30,000 exposures to OP compounds and more than 14,000 exposures to carbamates. Although these totals are large, the number of reported exposures to both insecticides has each dropped annually since 2002, likely due in part to a phase out of their residential use during this period.²⁰¹ However, the number of fatalities reported to the AAPCC remained constant, during this time averaging about five per year. These insecticides still rank as the most lethal insecticides in use in the United States and are among the most lethal poisonings (Chap. 136).

Since the overall case fatality for OP and carbamate pesticide poisoning is on the order of 10% to 20%, the 200,000 deaths a year in rural Asia must represent 1 to 2 million poisonings. Respiratory failure is a major problem with OP and carbamate poisoning. Modeling suggests that the 20% to 30% of patients who develop respiratory failure will receive 1,147,000 to 2,294,000 days of ventilation every year.⁹⁹ This will require constant use of 3140 to 6280 ventilators worldwide solely for managing self-poisoning with pesticides.⁹⁹ These figures for acute poisoning undoubtedly omit numerous unreported and possibly unrecognized illnesses resulting from lower level environmental exposure to these chemicals.

Typically, patients present following unintentional or suicidal ingestion of anticholinesterase insecticides or after working in areas recently treated with these compounds. Children and adults can develop toxicity while playing in or inhabiting a residence recently sprayed or fogged with OP insecticides by a pesticide applicator.²⁴¹ Direct dermal contact with certain types of these insecticides may be rapidly poisonous.¹⁴⁵ Outbreaks of mass poisoning regularly occur in the developing world, and less commonly in the United States, from contamination of crops or food.^{30,41,56,57,78,181,217} Epidemics of toxicity are also reported among groups illegally importing and using the potent carbamate aldicarb.^{159,175} Unfortunately, OPs and carbamates have also been used for homicide.^{26,54,184,205,220}

PHARMACOLOGY

Organic Phosphorus Compounds

OP poisoning results in a rise in the concentration of acetylcholine (ACh) at muscarinic and nicotinic cholinergic synapses, which, in turn, leads to the syndrome of cholinergic excess. **Figure 113–1** shows the basic formula for cholinesterase inhibiting OP compounds.^{88,207} The “X” or “leaving group” determines many of the characteristics of the compound and provides a means of classifying OP insecticides into four main groups (**Table 113–2**). Group 1 compounds contain a quaternary nitrogen at the X position and are collectively termed phosphorylcholines. These chemicals were originally developed as weapons of war, are powerful cholinesterase inhibitors, and can directly stimulate cholinergic receptors, presumably because of their structural resemblance to ACh. Group 2 compounds are called fluorophosphates because they possess a fluorine molecule as the leaving group. Like group 1 compounds, these compounds are volatile and highly toxic, making them well-suited for chemical warfare. The leaving group of group 3 compounds is a cyanide molecule or a halogen other than fluorine. The most well-known agents in this group are cyanophosphates, such as the chemical weapon tabun.

FIGURE 113–1 General structure of organic phosphorus insecticides. X represents the leaving group. R₁ and R₂ may be aromatic or aliphatic groups that can be identical.

TABLE 113–2. The Classification of Organic Phosphorus Compounds by Groups, Showing Leaving Groups and Examples of Each Group

Group 1—phosphorylcholines

Leaving group: substituted quaternary nitrogen

Echothiophate iodide

Group 2—fluorophosphates

Leaving group: fluoride

Dimetox, sarin, mipafox

Group 3—cyanophosphates, other halophosphates

Leaving group: CN⁻, SCN⁻, OCN⁻, halogen other than fluoride

Tabun

Group 4—multiple constituents

Leaving group:

Dimethoxy

Azinphos-methyl, bromophos, chlorothion, crotoxyphos, dikapthon, dichlorvos, dicrotophos, dimethoate, fenthion, malathion, mevinphos, parathion-methyl, phosphamidon, temephos, trichlorfon

Diethoxy

Carbophenothion, chlorfenvinphos, chlorpyrifos, coumaphos, demeton, diazinon, disulfoton, disulfoton, ethion, methidathion, parathion, phorate, phosolan, TEPP

Other dialkoxo

Isopropyl paraoxon, isopropyl parathion

Diamino

Schradan

Chlorinated and other substituted dialkoxo

Haloxon

Triethioalkyl

Merphos

Triphenyl and substituted triphenyl

Triorthocresyl phosphate (TOCP)

Mixed substituent

Crofosfate, cyanofenphos

Echothiophate iodide

Sarin

Tabun

Parathion

Triorthocresyl phosphate (TOCP)

The fourth group is the broadest and comprises various subgroups based on the configuration of the R₁ and R₂ groups, with the majority falling into the category of either a dimethoxy or diethoxy compound. Most of the insecticides in use today fall into this last class.⁸⁸

“Direct”-acting OP insecticides (“oxons”) inhibit acetylcholinesterase (AChE) without being metabolized in the body. However, many pesticides, such as parathion and malathion, are “indirect” inhibitors (prodrugs or “thions”) requiring partial metabolism (to paraoxon and malaaxon, respectively) within the body to become active. Desulfuration to the oxon occurs in the intestinal mucosa and liver following absorption.^{131,202}

The OPs bind to a hydroxyl group at the active site of the AChE enzyme. As the leaving group of the OP insecticide is split off by AChE, a stable but reversible bond results between the remaining substituted phosphate of the OP and AChE, effectively inactivating the enzyme (Figs. 113–2 and 113–3).

FIGURE 113–2 Normal metabolism of acetylcholine by acetylcholinesterase to choline and acetic acid.

FIGURE 113–3 Mechanism of inhibition of acetylcholinesterase by an organic phosphorus compound.

A dimethylated organic phosphorous pesticide (for example, methylparaoxon) inhibits AChE function by phosphorylating the serine hydroxyl group at the active site of the enzyme (reaction 1). This reaction occurs very quickly. Active AChE is subsequently regenerated by a hydroxyl ion attacking the acetylated serine residue, removing the phosphate moiety, and releasing active enzyme (reaction 2). This regenerative process, however, is much slower than inhibition, requiring hours to days to occur (spontaneous reactivation $t_{1/2} \sim 0.7\text{--}86$ hours for dimethyl and $31\text{--}57$ hours for diethyl compounds).

While in the inactive state, the enzyme is prone to “aging” (reaction 3) in which one alkyl side chain of the phosphoryl moiety is removed non-enzymatically, leaving a hydroxyl group in its place. “Aged” AChE can no longer react with water, and regeneration no longer occurs. This reaction occurs considerably faster with enzymes that have been inhibited by dimethylated pesticides ($t_{1/2} \sim 3.3$ hours) than those inhibited by diethylated pesticides ($t_{1/2} \sim 30$ hours).

The slower the regenerative process, the greater the quantity of inactive AChE available for aging. Pralidoxime catalyses the regeneration of active acetylcholinesterase by exerting a nucleophilic attack on the phosphoryl group, transferring it from the enzyme to itself. By speeding up reaction 2, it reduces the quantity of inactive AChE available for aging. However, because aging occurs more rapidly with dimethylated pesticides, pralidoxime is only useful before about 12 hours with dimethylated enzyme.

poisoning. *Hum Exp Toxicol*. 1997;16:466–472.

Worek F, Diepold C, Eyer P. Dimethylphosphoryl-inhibited human cholinesterases: Inhibition, reactivation, and aging kinetics. *Arch Toxicol*. 1999;73:7–14.

Although splitting of the choline-enzyme bond in normal ACh metabolism is completed within microseconds, the severing of the OP compound-enzyme bond is prolonged. The half-life of this reaction depends on the chemistry of the substituted phosphate. The *in vitro* half-life for spontaneous reactivation of human AChE inhibited by dimethoxy OPs is 0.7 to 0.86 hours, while that of diethoxy inhibition is 31 to 57 hours.⁸¹ Spontaneous reactivation is therefore far quicker with dimethoxy OPs.

Oximes, such as pralidoxime or obidoxime, markedly speed up the rate of reactivation.⁸¹ However, if the phosphate is allowed to remain bound to the AChE, because of late or inadequate administration of oximes, an alkyl group is non-enzymatically lost (Fig. 113–3)—a process called “aging.” Once aging has occurred, the AChE can no longer be reactivated by oximes. Again, the half-life of this reaction is determined by the substituted phosphate. The *in vitro* half-life of human AChE after poisoning with dimethoxy OPs is 3.7 hours, compared to 31 hours after diethoxy poisoning.⁸¹ Clinically, this means that patients who present to a hospital 4 hours after poisoning with a dimethoxy OP will already have 50% of their AChE irreversibly inhibited; after 14 hours, the patients will be completely refractive to oxime therapy. In contrast, patients poisoned by diethoxy OPs presenting within 14 hours will have very little aged AChE and should be responsive to oximes. De novo synthesis of AChE is required to replenish its supply once aging has occurred (see Diagnostic Testing section below).²⁰⁷

OPs also vary by lipid solubility,²¹ rate of activation (conversion from thion to oxon), rate of AChE inhibition,⁸¹ and relative inhibition of the plasma enzyme butyrylcholinesterase. Some OPs do not fulfill the usual dimethoxy or diethoxy classification and have one of the alkyl groups linked to the phosphate by a sulfur molecule, rather than oxygen (eg, profenofos, methamidophos). Aging seems to be particularly rapid for these OPs.^{65,76}

Carbamates. Carbamate insecticides are N-methyl carbamates derived from carbamic acid (Fig. 113–4)¹⁸ Medicinal carbamate compounds include physostigmine, pyridostigmine, and neostigmine.²⁰⁷ Xenobiotics such as meprobamate and various urethanes are carbamate derivatives, but do not inhibit cholinesterase. Thiocarbamate fungicides and herbicides (eg, maneb, zineb, nabam, and mancozeb) also do not inhibit AChE and do not produce the cholinergic toxic syndrome (Chap. 112).

FIGURE 113–4 General structure of carbamate insecticides.

When exposed to carbamates, AChE undergoes carbamylation in a manner similar to phosphorylation by OPs,²³¹ allowing ACh to accumulate in synapses. Aging cannot occur, and the carbamate-AChE bond hydrolyzes spontaneously, reactivating the enzyme. As such, the duration of cholinergic symptoms in carbamate poisoning is generally less than 24 hours. However, complications that result from the cholinergic syndrome, in particular aspiration, can last much longer.

PHARMACOKINETICS AND TOXICOKINETICS

Organic Phosphorus Compounds

OP insecticides are well absorbed from the lungs, gastrointestinal tract, mucous membranes, and conjunctiva following inhalation, ingestion, or topical contact.⁸⁸ Although absorption through intact skin appears to be relatively low,⁹⁴ percutaneous exposure to highly toxic compounds can cause severe toxicity.^{43,45,145,226} The presence of broken skin and dermatitis and higher environmental temperatures further enhances cutaneous absorption.⁸⁸

Poisonings can be chronic or acute, although the differentiation has little clinical relevance. The difficulty in removing these compounds from the skin and clothing may explain some chronic poisonings; inadequate skin and respiratory protection during pesticide application is responsible for many cases of occupational exposures.

The time to peak plasma concentration after self-poisoning is unknown. Human volunteer studies, using very low doses of chlorpyrifos, found C_{max} to be around 6 hours after oral ingestion.¹⁶⁰ However, patients ingesting large amounts of oxon or fast acting thion OPs can become symptomatic within minutes,^{79,138} suggesting that the onset of absorption is rapid.

Most OPs are lipophilic²¹ and are therefore predicted to have a large volume of distribution and to rapidly distribute into tissue and fat where they are protected from metabolism. Radiolabeled parathion injected into mice distributes most

rapidly into the cervical brown fat and salivary glands, with high concentrations also measured in the liver, kidneys, and ordinary adipose tissue.⁸⁶ Adipose tissue gradually accumulates the highest concentrations. Redistribution from these stores may allow for measurement of circulating insecticide concentrations for up to 48 days post-ingestion.^{49,90,187}

Cholinergic crisis may recur in patients when unmetabolized OPs are mobilized from fat stores.⁸⁸ The more lipophilic compounds such as fenthion and dichlofenthion (both with a log P {octanol/water coefficient} >4.0) are particularly likely to cause this phenomenon.^{49,69,148} Dimethoate, methamidophos, and oxydemeton methyl are three common OPs that are not lipophilic (log P <1.0), with predicted small volumes of distribution and high plasma OP concentrations.⁵⁰

The distribution of OPs into fat will likely include both activated and unactivated compound. When released from the fat hours to days later, the unactivated thion will require activation to cause clinical features.

Thion OPs are activated by cytochrome P450 enzymes in the liver and intestinal mucosa. The precise CYP450s responsible appears to vary according to the concentration of OP. For example, chlorpyrifos, diazinon, parathion, and malathion are all activated by CYP1A2 and 2B6 at low concentrations.^{33,34} However, at the higher concentrations more likely to occur after self-poisoning, CYP3A4 becomes dominant. The particular enzymes involved in metabolism of the active oxon to inactive metabolites are less clear.

Studies have investigated possible relationships between human plasma paraoxonase (PON) activity and susceptibility to acute and chronic effects of OP poisoning.^{44,194,196} Paraoxonase is an A-esterase that can hydrolyze the active (oxon) metabolites of some OP insecticides. Activity differs significantly among animal species. Some animal models of OP poisoning demonstrate protection from toxicity when exogenous PON is administered, and greater susceptibility to poisoning when enzyme-deficient animals (such as genetically engineered knockout mice) are exposed.¹⁹⁴ Some authors have postulated that genetic polymorphisms in human PON activity may lead to variations in interindividual susceptibility to some OP insecticides.⁴⁴

Carbamates. Carbamate insecticides are absorbed across skin and mucous membranes, and by inhalation and ingestion. Peak cholinesterase inhibition occurs within 30 minutes of oral administration in rats.¹⁶² Most carbamates undergo hydrolysis, hydroxylation, and conjugation in the liver and intestinal wall, with 90% excreted in the urine within 3 to 4 days¹⁸.

There is a view that carbamates, unlike OPs, do not easily enter the brain. However, carbamates cause CNS depression in humans,¹⁷⁵ have lipophilic log P values,²¹ and rat studies show inhibition of brain cholinesterases with multiple carbamates.¹⁶² Furthermore, post mortem studies have shown high concentrations of carbamates in CSF and brain.^{109,150,151} The evidence at present therefore suggests that in this aspect they do not differ markedly from OPs. One important distinction between carbamates and OPs is that the carbamate-cholinesterase bond does not “age.” Thus AChE inhibition is reversible, with spontaneous hydrolysis occurring usually within several hours.

PATHOPHYSIOLOGY

Acetylcholine is a neurotransmitter found at both parasympathetic and sympathetic ganglia, skeletal neuromuscular junctions, terminal junctions of all postganglionic parasympathetic nerves, post-ganglionic sympathetic fibers to most sweat glands, and at some nerve endings within the central nervous system (Fig. 113–5).²²⁸ As the axon terminal is depolarized, vesicles containing ACh fuse with the nerve terminal, releasing ACh into the synapse or neuromuscular junction (NMJ). Acetylcholine then binds postsynaptic receptors leading to activation (G proteins for muscarinic receptors and ligand-linked ion channels for the nicotinic receptors). Activation alters the flow of K⁺, Na⁺, and Ca²⁺ ionic currents on nerve cells, and alters membrane potential of the postsynaptic membrane, resulting in propagation of the action potential.

FIGURE 113–5 Pathophysiology of cholinergic syndrome as it affects the autonomic and somatic nervous systems. N = nicotinic; M = muscarinic.

OPs and carbamates are inhibitors of carboxylic ester hydrolases within the body, including variably acetylcholinesterase (AChE, EC 3.1.1.7), butyrylcholinesterase (plasma or pseudocholinesterase, BuChE, EC 3.1.1.8), plasma and hepatic carboxylesterases (aliesterases), paraoxonases (A-esterases), chymotrypsin, and other nonspecific proteases.³⁷

AChE hydrolyzes ACh into two inert fragments: acetic acid and choline. Under normal circumstances, virtually all ACh released by the axon is hydrolyzed almost immediately, with choline undergoing reuptake into the presynaptic terminal where it is reused to synthesize ACh.²²⁸ AChE is found in human nervous tissue and skeletal muscle, and on erythrocyte (RBC) cell membranes.¹⁴³ Acutely, RBC AChE activity correlates well with the function of nervous system AChE for some OPs.^{210,212} However, recent findings from profenofos poisoned humans⁷⁶ and dimethoate poisoned pigs⁷⁴ have raised questions about the validity of using AChE activity on RBCs as a marker of poisoning severity.⁸²

Butyrylcholinesterase is a hepatic derived protein that is found in human plasma, liver, heart, pancreas, and brain. Although the function of this enzyme is not well understood, its activity can be easily measured and has important clinical implications in anesthesia (Chap. 69).

Inhibition of AChE is generally thought to account for all, or the majority, of clinical features of both OP and carbamate poisoning. However, these compounds also inhibit many other enzymes.³⁷ The clinical effects of these interactions are not yet understood.

Patients also ingest formulated pesticides rather than the pure anticholinesterase compound or “active ingredient” (AI). OPs sold for agricultural use are typically emulsifiable concentrates (EC) in which the AI (eg, dimethoate) is mixed with an organic solvent such as xylene or cyclohexanone and a surfactant/emulsifier. Unfortunately, the compounds used for co-formulation are highly variable, being optimized by each pesticide manufacturer for each OP. As a result, co-formulants often differ between the same OP produced by two companies, and for two OPs produced by one company.

The clinical effect of poisoning with these co-formulants, in addition to the carbamate or OP, has not been completely evaluated and remains unclear. Complications of surfactant poisoning have been well described in glyphosate poisoning²⁸ (Chap. 112) but not with insecticides. The acute toxicity of the solvents appears to be low—for example, the rat oral LD₅₀s for xylene and cyclohexanone are 4000 to 5000 and 1620 mg/kg, respectively. However, in a minipig model of acute oral dimethoate EC40 poisoning, early respiratory arrest occurred at a point when red cell AChE was less than 30% inhibited, suggesting a non-AChE mechanism.⁷⁴ Early work showed that dimethoate toxicity could be increased markedly by changing the solvent³⁸; more recent work with chlorpyrifos has shown a modest change in toxicity after changing the solvent.²¹⁶ The minipig model has shown that the toxicity of dimethoate EC40 requires both the dimethoate AI and the cyclohexanone solvent. Changes in the solvent reduced toxicity.⁷⁴ While potentially important, the major differences in clinical syndrome noted in patients between dimethoate EC40, chlorpyrifos EC40, and fenthion EC50 cannot be attributed to the solvent since most pesticides are generic, using 40% xylene as the solvent.⁶⁹

A further effect of the solvents and surfactants occurs after aspiration. Ingestion of both OPs and carbamates can cause rapid loss of consciousness and respiratory arrest, increasing the risk of aspiration with pesticide AI, solvent, surfactant, and gastric contents. The relative role of gastric contents and pesticide is not yet clear. Aspiration pneumonitis is a major

clinical problem in OP poisoning and the treatment of the pneumonitis will not be achieved by the oximes and atropine.⁶³

Pesticides are frequently co-ingested with alcohol, particularly by men,^{130,219} raising questions about the effect of this alcohol on outcome after OP poisoning.⁶⁶ Analysis of a cohort of patients self-poisoned with dimethoate EC40 showed that the alcohol did not directly affect the clinical outcome of poisoning⁷¹; however, higher blood concentrations of alcohol were associated with higher blood concentrations of dimethoate, suggesting that inebriation caused people to drink larger amounts of pesticide, resulting in a worse outcome.

CLINICAL MANIFESTATIONS

Acute Toxicity—Organic Phosphorus Compounds

Clinical findings of acute toxicity from OPs derive from excessive stimulation of muscarinic and nicotinic cholinergic receptors by ACh in the central and autonomic nervous systems, and at skeletal neuromuscular junctions (Fig. 113–5). The classically described patient with severe OP poisoning is one who is unresponsive, with pinpoint pupils, muscle fasciculations, diaphoresis, emesis, diarrhea, salivation, lacrimation, urinary incontinence, and an odor of garlic or solvents. Less severe poisoning is often not so typical.

The timing of onset of symptoms varies according to the route, the degree of exposure, and particularly the OP. This is important since more rapid onset of poisoning will reduce the likelihood of the patient reaching health care safely, before need for intubation and ventilation, or onset of complications such as aspiration. Onset of respiratory failure outside of a hospital in most parts of the world will result in the patient's death.

Patients suffering massive ingestions can become symptomatic as quickly as 5 minutes following ingestion. Most patients with acute poisoning become symptomatic within a few hours of exposure, and practically all who will become ill show some features within 24 hours.

Oxon OPs (such as mevinphos and monocrotophos) are already active on exposure, and patients become symptomatic very soon after ingestion. One man was reported to have died within 15 minutes of mevinphos ingestion.¹³⁸ Some thion OPs are very rapidly converted to oxons and can similarly produce symptoms rapidly—patients ingesting parathion can be unconscious within minutes.⁷⁹ In contrast, patients ingesting thions that are slowly converted to active oxons (such as fenthion) may not show symptoms for hours.

The speed of onset will also be affected by the quantity ingested and the toxicity⁸¹ of the OP. Patients ingesting very large doses or less toxic pesticides or small doses of highly toxic pesticides will rapidly inhibit a clinically significant proportion of their AChE and exhibit features earlier.

Lipid solubility also likely affects time to onset. Fat soluble OPs (with log P of >3–4) will rapidly distribute to fat stores, in the process reducing their concentration in extracellular fluid where they impart their clinical effect (eg, fenthion⁶⁹). Significant poisoning with such OPs is commonly delayed as respiratory failure with fenthion, for example, typically occurs after 24 hours, in contrast to less fat soluble OPs.⁷³

Symptoms following OP exposure may last for variable lengths of time, again based on the compound and the circumstances of the poisoning. For example, the more lipophilic compounds, such as dichlofenthion or fenthion, can cause recurrent cholinergic effects for many days following oral ingestion as they are released from fat stores.^{49,148,172}

A variety of CNS findings are reported after exposure. Many patients present awake and alert, complaining of anxiety, restlessness, insomnia, headache, dizziness, blurred vision, depression, tremors, or other nonspecific symptoms.^{17,158} The level of consciousness may deteriorate rapidly to confusion, lethargy, and coma, and patients may display inappropriate behavior. Where careful observational studies have been done, convulsions appear to be uncommon in OP pesticide poisoning compared to OP nerve agent poisoning.^{69,122} The few convulsions that do occur may be due to hypoxia as a complication of acute cholinergic poisoning.

The effects of excessive ACh on the autonomic nervous system may be variable because cholinergic receptors are found in both the sympathetic and parasympathetic nervous systems (Fig. 113–5). Excessive muscarinic activity can be characterized by several mnemonics, including “SLUD” (salivation, lacrimation, urination, defecation) and “DUMBBELS” (defecation, urination, miosis, bronchospasm or bronchorrhea, emesis, lacrimation, salivation). Of these, miosis may be the most consistently encountered sign. Bronchorrhea can be so profuse that it mimics pulmonary edema.¹⁵⁸

Although muscarinic findings are emphasized in these mnemonics, muscarinic signs may not always be clinically dramatic or initially predominant. Parasympathetic effects can be offset by excessive autonomic activity from stimulation of nicotinic adrenal receptors (resulting in catecholamine release) and postganglionic sympathetic fibers.²⁰⁷ Mydriasis, bronchodilation, and urinary retention can occur as a result of sympathetic activity. Increased sympathetic activity usually precipitates white blood cell demargination, resulting in leukocytosis.^{156,158}

Excessive adrenergic influences on metabolism cause glycogenolysis²⁰⁸ with hyperglycemia and ketosis that have been mistaken for diabetic ketoacidosis.^{146,238} Hypoglycemia can also occur, although the mechanism is unclear.¹¹⁴ Disturbances

of glucose metabolism do not seem to be common. Two studies of patients with OP or carbamate poisoning showed hyperglycemia in 6% to 8%.^{105,195} It is possible that effects on glucose metabolism may be associated with specific OPs, such as the malathion¹¹⁴ and diazinon,¹⁸⁸ rather than all OPs. Larger cohorts of patients exposed to single OPs are required to determine whether such associations exist.

Hyperamylasemia appears to be relatively common in OP poisoning, occurring in 4/47 (9%) adults in one series¹⁸⁶ and 5/17 (29%) children in a second.²²⁵ However, both included various anticholinesterase pesticides; a series of only malathion poisoned patients reported hyperamylasemia in 47/75 (63%).⁴⁶ The amylase likely comes from the pancreas since animal studies show OP-induced damage¹¹⁵ and human poisoning cases show associated pancreatic edema and, rarely, necrotizing pancreatitis.^{29,103,165} The incidence of subclinical and clinical pancreatitis probably varies according to the OP ingested and perhaps the co-formulants. Elevations of hepatic enzymes can also occur following OP pesticide exposures.^{161,174,239}

Cardiovascular manifestations reflect mixed effects on the autonomic nervous system (including increased sympathetic tone), together with the consequences of OP-induced hypoxia and hypovolemia. Admission heart rate is usually normal, with relatively few patients expressing a tachycardia or bradycardia. Patients who have received atropine before admission may be tachycardic. The literature is filled with reports of QT prolongation and ventricular dysrhythmias.^{15,95,128,183,185} However, these reports are complicated by the fact that most patients had an ECG done before they received any atropine to counter the cholinergic syndrome or were so ill that atropine was ineffective. The first is illustrated by a description of 46 patients with OP or carbamate poisoning in which “ECG recordings [were] taken on arrival ... before the start of atropine treatment.”¹⁸⁵ The reported cardiac rhythms may be confounded by the hypoxia and hypovolemia that characterize the cholinergic syndrome. In another study, 29 of the 35 patients with such dysrhythmias died.¹⁴⁰ In contrast, when more than 1000 patients poisoned with WHO Class II OPs were evaluated, serious dysrhythmias were very rare in patients adequately resuscitated with oxygen, atropine, and fluids (Eddleston, unpublished data).

Hypotension may occur because of stimulation of vascular receptors by excessive circulating Ach, severe volume loss, or myocardial dysfunction.^{11,124} Severe hypotension is a particularly significant problem in poisoning with the unusually fat-insoluble OP dimethoate.^{50,69} Fatal poisoning is characterized by early respiratory failure followed by hypotension that can be treated only transiently with vasopressors. Such a syndrome was not found in poisoning with fat-soluble OPs such as chlorpyrifos and fenthion.⁶⁹ The exact role of direct cardiotoxicity and peripheral vasodilation is not yet clear, or whether this syndrome occurs with other fat-insoluble OPs, such as methamidophos and oxydemeton methyl.⁵⁰ Recent studies indicate that the solvent in branded dimethoate EC40, cyclohexanone, is partially responsible for this severe hypotension.⁷⁴

Respiratory complications of OP poisoning include the direct pulmonary effects of bronchorrhea and bronchoconstriction, neuromuscular junction failure in the diaphragm and intercostal muscles, and loss of central respiratory drive.⁵³ If severe and occurring before patients reach medical care, these effects will lead to hypoxemia and respiratory arrest, the most common cause of death after OP poisoning.⁸⁸ Both bronchorrhea and bronchoconstriction respond to adequate atropine therapy. Unfortunately, neither neuromuscular junction failure nor loss of central respiratory drive respond to atropine, and patients must be intubated and ventilated until respiratory function returns.

An additional early respiratory complication is hydrocarbon aspiration that may occur after ingestion of commercially formulated pesticides. The incidence of aspiration and the consequences of aspiration—whether chemical pneumonitis, pneumonia, or acute respiratory distress syndrome—are not yet known and likely differ according to the OP and formulation ingested.

Acetylcholine stimulation of nicotinic receptors also governs skeletal muscle activity. The effects of excessive cholinergic stimulation at these sites are similar to that of a depolarizing neuromuscular blocker (succinylcholine) and initially result in fasciculations or weakness. Although this effect is often considered to be the most reliable sign of parathion toxicity,¹⁵⁸ it is the author’s clinical experience that many patients severely poisoned with other OP insecticides do not display this sign. Acute cranial nerve abnormalities are uncommon.

Severe poisoning results in paralysis.²²³ Rarely, patients may present with paralysis from nicotinic effects without any other initial signs and symptoms suggestive of OP toxicity.^{84,92} Extraparal effects such as rigidity and choreoathetosis occur uncommonly after severe anticholinesterase poisoning but can persist for several days after cholinergic features have resolved.^{9,25,134,153}

Acute Toxicity—Carbamates. The acute effects of poisoning from carbamate insecticides appear identical to those of OP insecticides except for the relative short duration of cholinergic features due to rapid hydroxylation of the carbamate-AChE bond. Persistent cholinergic features are not reported for carbamate poisoning.

Chronic Toxicity

Illness may result from chronic exposure to excessive amounts of OP insecticides. Chronic exposure most commonly occurs in workers who have regular contact with OPs, but may also occur in individuals who have repeated contact with excessive

amounts of insecticides in their living environments. Cholinergic ophthalmic preparations can lead to toxicity in this manner.¹⁴¹ Although tolerance to acute cholinergic systemic effects of OP insecticides (including death in rats) may be observed with long-term exposures,⁸⁸ persons who have such repeated contact may begin to describe symptoms after substantial lengths of time. These effects can range from vague neurological complaints, such as weakness and blurred vision, to miosis, nausea, vomiting, diarrhea, diaphoresis, and other cholinergic effects.^{6,7,141,198} Butyrylcholinesterase activity is usually the most sensitive measure of exposure, and workers in contact with these chemicals should have baseline butyrylcholinesterase testing for comparison and monitoring.^{88,110}

Recent literature has linked Parkinson disease with chronic exposure to pesticides including OP insecticides.^{58,199} Some individuals may have a possible genetic susceptibility.²⁵ Additionally, significant acute exposures to OP insecticides can lead to self-limited movement disorders resembling Parkinson disease that resolve over weeks to months (see above). Although statistics derived from some epidemiologic studies suggest the connection,^{77,108} other studies have failed to find an association between OP compounds and Parkinson disease.²⁰⁶ All studies thus far have been retrospective in nature and therefore likely confounded by recall bias.

Delayed Syndromes

Neuromuscular Junction Dysfunction. A syndrome of delayed muscle weakness without cholinergic features or fasciculations resulting in respiratory failure was first reported by Wadia in 1974 as type II paralysis²²³ and further refined by Senanayake and Karalliedde in 1987 as the intermediate syndrome.¹⁹⁰ The syndrome is defined as occurring 24 to 96 hours after acute OP poisoning, and after resolution of the cholinergic crisis.^{125,190,223} Patients develop proximal muscle weakness, especially of the neck flexors, and cranial nerve palsies and progress to respiratory failure that may last for several weeks.¹²⁵ Consciousness is preserved unless complicated by hypoxia or pneumonia. The syndrome is important since apparently stable patients can suddenly develop a respiratory arrest; all patients must be evaluated for muscle weakness if deaths are to be prevented.^{20,166} The first sign is often weakness of neck flexion such that patients cannot lift their head off the bed.

Although the exact pathophysiology of the syndrome is unknown, it is clearly due to dysfunction of the neuromuscular junction, with respiratory failure resulting from weakness affecting the diaphragm and intercostal muscles. Preservation of consciousness suggests that the central respiratory drive is not involved. Clinicians have proposed that overwhelming NMJ stimulation causes downregulation of the NMJ synaptic machinery.^{52,190} This would require time to be repaired, even after the pesticide has been removed from the body, explaining the long duration of ventilation needed by many patients.⁷³

Cases and small case series are reported from around the world, with resulting comments that the intermediate syndrome is more common with certain OPs, such as parathion, methyl parathion, malathion, and fenthion. Unfortunately, large cohorts of poisoning with specific OPs receiving standardized treatments are rarely reported, making comparisons of incidence between OPs difficult. However, two cohorts have shown that the intermediate syndrome causing respiratory failure is more common in fenthion poisoning than chlorpyrifos, malathion, or fenitrothion poisoning.^{73,222}

Clinical examination remains the most reliable means of identifying the occurrence of intermediate syndrome.¹²⁵ Electromyograms will often show tetanic fade in these patients, and suggest both pre- and postsynaptic involvement.¹²⁵ Recent work has noted characteristic electrophysiological features that can be identified before onset of neurological features and respiratory paralysis.¹¹⁷ The majority of patients developing weakness in this series did not progress to respiratory failure, indicating that intermediate syndrome is a spectrum disorder.

Another study of severely poisoned patients suggested that the occurrence of intermediate syndrome strongly correlated with the initial degree of cholinergic crisis and seemed to be a continuum with the neuromuscular paralysis resulting from the early stages of poisoning.¹¹⁸ This view is supported by early work⁵² and a more recent study of dimethoate poisoning which showed that peripheral NMJ dysfunction can occur simultaneously with the cholinergic syndrome.⁷³ Patients with moderate to severe dimethoate poisoning typically require intubation for respiratory failure soon after ingestion, during the acute cholinergic syndrome. However, this is relatively short-lived, and patients recover consciousness after a few days. As the cholinergic syndrome settles and the patients regain consciousness, with recovery of the central respiratory drive, they are still unable to ventilate. Similar to patients with classical intermediate syndrome, they require ventilatory support for several weeks until their NMJ recovers function. In addition, this case series showed that the classic intermediate syndrome—respiratory failure after resolution of the cholinergic syndrome—can occur before 24 hours and after 96 hours.⁷³

These studies suggest that the original intermediate syndrome is just one important aspect of OP-induced peripheral NMJ dysfunction. It seems likely that the relative incidence and timing of the intermediate syndrome or delayed NMJ dysfunction for different OPs is determined by the rapidity and quantity of AChE inhibition. Where inhibition is intense, with fat-insoluble OPs like dimethoate that have very high plasma concentrations, NMJ dysfunction comes on early, before recovery from the cholinergic crisis. Fat-soluble OPs, such as fenthion, cause a more protracted AChE inhibition, likely

explaining why fenthion-induced NMJ dysfunction and respiratory failure occur later.⁷³

Some authors have suggested that insufficient oxime therapy explains the intermediate syndrome.²² Of note, AChE inhibited by dimethoate or fenthion responds poorly to oximes, in contrast to chlorpyrifos, which responds well to oximes and has a lower incidence of intermediate syndrome.^{69,73} The occurrence of NMJ dysfunction in chlorpyrifos poisoning may well be due to inadequate oxime therapy. However, adequate oxime therapy after, for example, malathion poisoning,²⁰⁰ may be irrelevant since this dimethyl OP responds poorly to oximes. Regardless, delayed NMJ dysfunction may be due to ineffective AChE reactivation, whether due to inadequate doses or to poisoning with OPs that do not respond to oxime therapy.

Recent animal studies of dimethoate poisoning may shed further light on this condition. These studies produced NMJ dysfunction and showed that it did not occur after poisoning with dimethoate active ingredient alone. However, it did occur after poisoning with the agricultural EC40 formulation that included both the dimethoate active ingredient and its solvent, cyclohexanone.⁷⁴ This raises the possibility that NMJ dysfunction is due to an interaction of solvent and active ingredient. All reported cases have occurred after poisoning with agricultural formulations of OP insecticides; further studies are required to clarify the role of solvents and the possible mechanisms of their effects.

The treatment of intermediate syndrome is supportive with airway protection and mechanical ventilation. There are no substantial data demonstrating that pralidoxime or atropine is effective in the treatment of this disorder, although patients may require these medications to control concurrent cholinergic symptoms. The weakness and paralysis commonly resolve in 5 to 18 days.^{73,106,117,118}

Organic Phosphorous Compound-Induced Delayed Neuropathy (OPIDN). Peripheral neuropathies can occur with chronic OP pesticide exposures days to weeks following acute exposures. OPIDN results from inhibition by phosphorylation of the enzyme neuropathy target esterase (NTE, now identified as a lysophospholipase) within nervous tissue.^{36,91,119,120} This enzyme catalyzes breakdown of endoplasmic reticulum-membrane phosphatidylcholine, the major phospholipid of eukaryotic cell membranes. Neuropathic OPs cause a transient loss of NTE activity, putatively disrupting membrane phospholipid homeostasis, axonal transport, and glial-axonal interactions.⁹¹

Such neuropathies may result from exposure to OPs that do not inhibit red blood cell cholinesterase or produce clinical cholinergic toxicity.³⁹ The more commonly implicated chemicals include triaryl phosphates, such as triorthocresyl phosphate (TOCP), and dialkyl phosphates, such as mephosfolan, mipafox, and chlorpyrifos.¹²⁰ Pathologic findings demonstrate effects primarily on large distal neurons, with axonal degeneration preceding demyelination.

Contaminated foods and beverages were responsible for epidemics of OP compound-induced delayed polyneuropathies and encephalopathy. In the 1930s, thousands of individuals in the United States became weak or paralyzed after drinking a supplement containing TOCP—an outbreak nicknamed “ginger Jake paralysis”^{10,149} (Chap. 2). Contaminated cooking and mineral oils were responsible for outbreaks of delayed polyneuropathies in Vietnam and Sri Lanka.^{56,189} Vague distal muscle weakness and pain are often the presenting symptoms and may progress to paralysis.⁹⁷ The administration of atropine or pralidoxime does not alter the onset and clinical course of these symptoms.²²¹ Pyramidal tract signs can appear weeks to months after acute exposures. Electromyograms and nerve conduction studies may be helpful in diagnosing this disorder by identifying the type of neuropathy (such as axonopathy, myelinopathy, or transmission neuropathy) and differentiating it from similar presentations such as Guillain-Barré syndrome.² Recovery of these patients is variable and occurs over months to years, with residual deficits common.^{149,189}

Delayed neuropathies are not usually associated with carbamate insecticides. One reason for this difference is presumed to be that aging of the neuropathy target esterase pesticide complex is a requirement for neuronal degeneration. Paradoxically, one study suggested that subgroups of carbamates may actually bind neuropathy target esterase and exert a protective effect against more toxic OP compounds.⁵ However, several cases of possible delayed neuropathy associated with carbamates have been reported.^{59,218,237} These cases involved ingestions of carbaryl, m-tolyl methyl carbamate, and carbofuran, included both sensory and motor tracts, and tended to resolve over 3 to 9 months. EMG findings were variable.

Behavioral Toxicity

Behavioral changes may also occur after acute or chronic exposure to OP compounds.⁸⁰ Signs and symptoms include confusion, psychosis, anxiety, drowsiness, depression, fatigue, and irritability. Electroencephalographic changes may be noted and can last for weeks.⁹⁶ Single photon emission computed tomography (SPECT) scanning revealed morphologic changes in the basal ganglia of one child following poisoning.²⁷ Recent studies have shown a deficit in cognitive processing after acute OP self-poisoning that lasts for at least 6 months and is not found in matched patients who had poisoned themselves with paracetamol.^{47,48} Thus far there appears to be no clear evidence for neuropsychiatric deficits resulting from subclinical exposure to OPs, although multiple small studies have suggested some effects.^{80,182}

DIAGNOSTIC TESTING

Organic Phosphorus Compounds

When confronted with a patient in cholinergic crisis who presents with a history of acute exposure to an OP cholinesterase inhibitor insecticide, the diagnosis is straightforward. Although textbooks list a variety of clinical signs for the cholinergic crisis (DUMBELS, SLUD—see above), most patients with significant poisoning can be simply identified by the presence of pinpoint pupils, excessive sweat, and breathing difficulty.⁶⁷ However, when the history is unreliable or does not suggest poisoning, the physician must turn to other means to confirm the diagnosis of OP or carbamate poisoning. Treatment of an ill patient with a cholinergic syndrome should not await confirmation of diagnosis.

The most appropriate laboratory tests for confirming cholinesterase inhibition by insecticides are tests that measure (1) specific insecticides and active metabolites in biologic tissues and (2) cholinesterase activity in plasma or blood. Unfortunately, although urine and serum assays for OP compounds and their metabolites are available,³ such testing is rarely obtainable within hours. Moreover “normal” ranges and toxic concentrations are not established for most compounds. Therefore, verifying cholinesterase inhibitor poisoning currently relies on measurement of cholinesterase activity.^{65,88}

Cholinesterase Activity. The two cholinesterases commonly measured are butyrylcholinesterase (BuChE, plasma cholinesterase, EC 3.1.1.8) and red cell acetylcholinesterase (AChE, EC 3.1.1.7). The former is produced by the liver and then secreted into the blood, where it metabolizes xenobiotics, including succinylcholine, pyrethroid insecticides, and cocaine. Red cell AChE is expressed from the same gene as the enzyme found in neuronal synapses. The main difference is in their mechanism of membrane attachment which is due to post-translational modification (red cell AChE is GPI-linked to the red cell while neuronal AChE forms dimers and tetramers that are attached to the postsynaptic membrane by other proteins¹⁴³). Inhibition of either red cell AChE or BuChE only serves as markers for cholinesterase inhibitor poisoning, as inhibition of these enzymes does not contribute to signs and symptoms of poisoning. However, in some cases, red cell AChE activity seems to reflect AChE activity in the NMJ soon after poisoning.²¹²

There is tremendous interindividual and interchemical variability in the degree and duration with which the OP insecticides affect particular cholinesterases. After a significant exposure, butyrylcholinesterase activity usually falls first, followed by a decrease in red blood cell AChE activity. The sequence may be highly variable, but by the time patients present with acute symptoms, activities of both cholinesterase have usually fallen well below baseline values.¹⁵⁸ Of note, the presence of BuChE, AChE, and other esterases varies markedly between species,¹³⁵ complicating the interpretation of animal studies. Furthermore, AChE occurs at very low concentrations in human plasma; therefore, papers citing human serum acetylcholinesterase activity^{13,215} are likely measuring serum BuChE.

Butyrylcholinesterase. BuChE activity usually recovers before red blood cell AChE activity, returning to normal within a few days after a mild exposure in the absence of a repeat exposure to the inciting agent.⁴⁵ However, BuChE activity is less specific for exposure than is red cell AChE activity.⁸⁸ Low BuChE activity can be found in patients with a number of disorders, including hereditary deficiency of the enzyme, malnutrition, hepatic parenchymal disease, chronic debilitating illnesses, and iron deficiency anemia.¹²⁶

The wide normal range of BuChE activity allows for patients with high normal values to suffer significant falls in activity, yet still register near normal BuChE activity on laboratory assay.⁴⁵ Additionally, day-to-day variation in the activity of this enzyme in healthy individuals may be as high as 20%.⁸⁸

Furthermore, since BuChE inhibition varies between OPs and does not cause clinical effects, an admission value by itself is of little value in predicting outcome. An admission value can only be used to predict outcome if the ingested OP is known and its clinical usefulness has been studied specifically for this OP.⁷⁰ For example, most patients who die with chlorpyrifos poisoning have a BuChE activity of around zero on admission; however, since chlorpyrifos is a very potent BuChE inhibitor, many other chlorpyrifos poisoned patients who do not die also present with very low BuChE activities. In contrast, since dimethoate is a poor inhibitor of BuChE, the majority of patients who die from dimethoate poisoning have a BuChE activity higher than many chlorpyrifos poisoned patients who remain clinically well.⁷⁰

Red Blood Cell Acetylcholinesterase. Red blood cell (RBC) AChE activity is thought to more accurately reflect nervous tissue AChE activity because the AChE in red blood cells is true AChE. Some authors suggest that clinical OP pesticide poisoning occurs when RBC AChE activity falls to below 50% of baseline values.¹⁵⁸ Neuromuscular dysfunction is typically associated with a value of 30% of normal or less.²¹² A major advantage of RBC AChE is that its activity can be related to blood hemoglobin (Hb) concentration, reducing variation due to varying hematocrits.²³⁴ Most people have a normal value of 600 to 700 mUnit/ μ mol Hb; a small study of Caucasians reported a mean of 651 with an SD of ± 18 mUnit/ μ mol Hb.²³⁴

After poisoning, and in the absence of oximes, RBC AChE may take many weeks to recover since erythrocytes in circulation at the time of OP exposure must be replaced. An average of 66 days may be necessary for RBC AChE activity to recover following severe inhibition (assuming no treatment with oxime), and activity may take up to 120 days to return to

normal. Rat studies suggest that neuronal AChE activity may return to normal more rapidly than RBC AChE.⁹⁸ Patients have been reported with normal NMJ activity and no cholinergic features, yet still have low RBC AChE laboratory values. For this reason, in subacute poisoning with OP agents, it is difficult to accurately predict the actual time of onset or duration of exposure when only the RBC AChE activity is known.

Depressed RBC AChE activity may be the result of exposures or conditions other than OP or carbamate poisoning, for example, in pernicious anemia and during therapy with antimalarial or antidepressant medicines (Table 113–3).^{127,152}

TABLE 113–3. Interpreting Cholinesterase Activity Values

	<i>Red Blood Cell Acetylcholinesterase</i>	<i>Butyrylcholinesterase</i>
Advantage	Better reflection of synaptic inhibition	Easier to assay, declines faster
Site	RBC (reflects CNS gray matter, motor end plate)	CNS white matter, plasma, liver, pancreas, heart
Regeneration (untreated)	1%/day	25%–30% in first 7–10 days
Normalization (untreated)	35–100 days	28–42 days
Use	Unsuspected prior exposure with normal butyrylcholinesterase	Acute exposure
False depression	Pernicious anemia, hemoglobinopathies, antimalarial treatment, oxalate blood tubes	Liver dysfunction, malnutrition, hypersensitivity reactions, drugs (succinylcholine, codeine, morphine), pregnancy, or deficiency

Recently, patients with acute profenofos poisoning have been noted to have complete inhibition of their RBC AChE activity without any cholinergic or neuromuscular signs.⁷⁶ Similarly, in an animal model, RBC AChE activity does not always reflect clinical severity, perhaps here due to the role of co-formulated solvents.⁷⁴ It is therefore unclear at present how useful RBC AChE activity is in grading poisoning severity.⁸²

Blood samples for cholinesterase activity must be obtained in the appropriate blood tubes. Tubes containing fluoride will permanently inactivate the enzymes, yielding falsely low activities, and should never be used. Specimens for RBC AChE are usually drawn into tubes containing a chelating anticoagulant such as EDTA to prevent clot formation. BuChE does not require an anticoagulant and can be drawn into a tube without chelators or anticoagulants.

Of note, OPs and oximes in collected blood samples will continue to interact with red cell AChE; small differences in time between sampling and assay can result in marked artificial variation in results. The most accurate way to take blood for AChE activity measurement is to immediately dilute it 1:20 or 1:100 into 0.9% sodium chloride solution or water cooled to 39°F (4°C) at the bedside, before rapidly freezing the sample. This process slows down both inhibitory and reactivating reactions in the tube, allowing more uniform results.^{65,234} Such rapid reactions do not occur with BuChE, and bedside dilution and cooling are therefore not required.

Protein Adducts. Current research is attempting to find ways of detecting OP exposure many weeks after the event. New techniques using mass spectrometry aim to identify phosphorylated proteins, such as albumin or BuChE, in blood samples.^{168,203}

Carbamates

Carbamates inhibit neuronal AChE, RBC AChE, and BuChE. The relative ease with which spontaneous decarbamylation of AChE takes place may result in the measurement of relatively normal RBC AChE activity despite severe cholinergic symptoms if the assay is not performed within several hours of sampling.¹⁵⁹ This emphasizes the importance of cooling and freezing the blood sample within minutes of collection (see above). As with OP pesticide poisoning, the wide “normal” range of BuChE activity makes interpretation of BuChE activity difficult at times when the patient’s baseline values are unknown. Unlike OP insecticides, carbamates generally do not produce persistently depressed RBC AChE and BuChE activities.

Atropine Challenge

An atropine challenge may be helpful in diagnosing cholinergic poisoning in a patient who presents with findings suggestive of this disorder, but in whom no history is available to suggest exposure to an OP or carbamate insecticide. In such individuals, a test dose of 1 mg of atropine in adolescents or adults, or 0.05 mg/kg in children up to an adult dose, should produce classic antimuscarinic findings, in particular tachycardia, mydriasis, and dry mucous membranes. Conversely, the persistence of cholinergic signs and symptoms after an atropine challenge strongly suggests the presence of anticholinesterase poisoning.¹⁵⁸ However, some patients suffering from mild anticholinesterase poisoning may respond to this dose of atropine. Therefore, the reversal of cholinergic findings does not completely exclude poisoning by one of these compounds.

Electromyogram (EMG) Studies

Although measuring cholinesterase activity is the test most often used to estimate tissue and neuronal AChE activity, studies support the use of repetitive nerve stimulation testing as an accurate method of quantifying AChE inhibition at the neuromuscular junction.^{12,23,117} Spontaneous repetitive potentials or fasciculations following single-nerve stimulation resulting from persistent ACh at nerve terminals can be a sensitive indicator of AChE inhibition at the motor endplate, and may be useful in the early diagnosis of anticholinesterase poisoning.²³ This type of evaluation may also be of benefit in early detection of rebound cholinergic crisis caused by continued insecticide absorption or redistribution from adipose, or onset of an intermediate syndrome.^{12,23,117}

Differential Diagnosis

The differential diagnosis for cholinergic poisoning includes three main categories (Table 113–4). The first comprises insecticides and other non-insecticidal cholinesterase inhibitors including the medicinal anticholinesterases neostigmine, pyridostigmine, physostigmine, and echothiophate iodide. The most common patients to suffer cholinergic poisoning syndrome from medicinal cholinesterase inhibitors are patients with myasthenia gravis who are given excessive doses of pyridostigmine. This entire group of xenobiotics should produce low butyrylcholinesterase and low RBC AChE activity. Newer agents used to treat Alzheimer disease, such as donepezil, may inhibit AChE, but symptomatic overdose of these agents appears rare.

TABLE 113–4. Categories of Cholinergic Poisoning

Cholinesterase inhibitors
Carbamate insecticides
Carbamate medicinals
Organic phosphorus insecticides
Organic phosphorus ophthalmic medications
Cholinomimetics
Acedidine
Bethanechol
Carbachol
Methacholine
Muscarine-containing mushroom
Pilocarpine
Nicotine alkaloids
Coniine
Lobeline
Nicotine

The second category of compounds that produce a syndrome of cholinergic poisoning includes agents with cholinomimetic activity. These compounds directly stimulate muscarinic or nicotinic cholinergic receptors, but do not inhibit AChE. In exposed individuals, BuChE and RBC AChE activity should be normal. Cholinomimetic medications include preparations of carbachol, methacholine, pilocarpine, and bethanechol. Nonpharmaceutical agents such as muscarine-containing mushrooms can be cholinomimetic (Chap. 120). Finally, a third group of xenobiotics, the nicotine alkaloids (eg, nicotine, lobeline, and coniine) cause CNS, autonomic, and skeletal muscle symptoms similar to those occurring in OP and carbamate toxicity (Chap. 85).

MANAGEMENT

Organic Phosphorus Insecticides

The primary cause of death after anticholinesterase poisoning is respiratory failure and hypoxemia. This results from muscarinic effects on the cardiovascular and pulmonary systems (bronchospasm, bronchorrhea, aspiration, bradydysrhythmias, or hypotension), nicotinic effects on skeletal muscles (weakness and paralysis), loss of central respiratory drive, and, rarely, seizures. Therefore, initial treatment for a patient exposed to OP compounds is directed at ensuring an adequate airway and ventilation, and at stabilizing cardiorespiratory function by reversing excessive muscarinic effects.^{65,67} Seizures not secondary to hypoxemia are treated with standard anticonvulsants such as benzodiazepines.

Maintenance of the patient's airway is best assured by early endotracheal intubation, and by positive pressure ventilation in patients who are comatose, have significant weakness, or who are unable to handle copious secretions that may accompany the poisoning. Only a neuromuscular blocker that is not primarily metabolized by cholinesterases should be used to induce pharmacologic paralysis if needed. The duration of action of the depolarizing agent succinylcholine and the nondepolarizing agent mivacurium, for example, will be extended in the presence of low BuChE activity, resulting in paralysis that can be prolonged for several hours.^{170,191,192}

Antimuscarinic Therapy. Simultaneously, excessive muscarinic activity should be controlled since this will aid respiration and oxygenation. Atropine competitively antagonizes ACh at muscarinic receptors to reverse excessive secretions, miosis, bronchospasm, vomiting, diarrhea, diaphoresis, and urinary incontinence^{87,107,158}

For adolescents and adults, intravenous doses should begin with boluses of 1 to 3 mg depending on the severity of symptoms; doses for children should start at 0.05 mg/kg up to adult doses. Although many authors state that repeat doses of 1 to 5 mg should be given every 2 to 20 minutes until "atropinization" occurs,⁶⁴ the most rapid method of obtaining control is to give doubling doses every 5 minutes if the response to the previous dose has been inadequate.⁶⁴⁻⁶⁷

This approach, of doubling or incremental doses, was tested against a standard bolus dose approach in a randomized controlled trial.¹ Patients were randomized to receive either 2 to 5 mg of atropine (depending on severity), repeated every 10 to 15 minutes as required, or 1.8 to 3 mg of atropine (depending on severity) followed by doubling doses every 5 minutes as required. Atropine doses were continued until all clinical signs of "atropinization" (see below) were clearly evident; atropine was given as further bolus doses at increasing intervals or as a constant infusion, respectively. All patients received pralidoxime (1–2 g q8–12h). The incremental approach was associated with reaching atropinization at 24 minutes versus 152 minutes with standard bolus dosing, despite administration of similar total doses of atropine (136 mg versus 109 mg, respectively). This faster administration of atropine was likely associated with more rapid resuscitation and stabilization as shown by the improved outcome: mortality with bolus atropine was 22.5% (18/80) and with incremental atropine was 8% (6/75) ($P < 0.05$). Incremental dosing was also associated with less atropine toxicity, less neuromuscular failure, and less requirement for ventilation.¹

"Atropinization" is classically said to occur when patients exhibit dry skin and mucous membranes, decreased or absent bowel sounds, tachycardia, reduced secretions, no bronchospasm (in absence of other causes such as aspiration), and usually, mydriasis.⁶⁴ However, patients die from cardiorespiratory compromise, not wet skin or miosis. Therefore, cardiorespiratory parameters, not pupil size or the presence of sweating, should guide administration of atropine. Atropine dosing should aim to reverse bronchorrhea and bronchospasm and to provide adequate blood pressure and heart rate for tissue oxygenation (for example, systolic BP >90 mmHg and heart rate >80 bpm). All can be easily and rapidly assessed.

Once atropinization occurs, it can be maintained by a constant infusion of atropine, typically initially giving 10% to 20% of the total loading dose per hour (usually maximum 2 mg/h). Regular checks for signs of under- or over-atropinization should guide the use of further boluses followed by changes in the infusion rate, or discontinuation of the infusion.⁶⁷ Continuous infusions have been used for as long as 32 days in patients severely poisoned by very fat soluble OPs that continue to redistribute from the fat and freshly inhibit AChE.⁹⁰

Many texts have previously recommended not giving atropine until oxygen has been administered due to the risk of inducing ventricular tachydysrhythmias.^{4,176} If true, this would have serious implications for patients in developing nations or remote regions where oxygen is frequently unavailable and where the advice would delay administration of potentially life-saving atropine. However, the data that drove this advice is weak, being based upon just two human case reports^{83,104} and one dog study.²²⁹ Overall, there is currently little evidence to support withholding atropine until after oxygen administration and clear possibilities for harm.

The presence of marked tachycardia (>120–140 beats/min in a well-hydrated patient not withdrawing from alcohol), mydriasis, absent bowel sounds, and urinary retention may indicate over-atropinization or atropine toxicity. This is unnecessary and possibly dangerous due to associated hyperthermia, confusion, and agitation.⁶⁷ Tachycardia is not, however, an absolute contraindication to atropine therapy since it can result from hypovolemia, aspiration pneumonitis, or agitation. Isolated pulmonary manifestations may respond to administration of nebulized atropine or ipratropium, and this treatment can accompany parenteral administration of these medications. However, the risk/benefit of this organ specific

treatment has not yet been assessed.

Large doses of atropine may be needed to reverse the bronchospasm, bronchorrhea, and bradycardia associated with severe OP pesticide toxicity.¹⁵⁸ Some patients with mild symptoms need only 1 or 2 mg of atropine to reverse cholinergic toxicity, but the moderately poisoned adolescent or adult commonly requires total doses as large as 40 mg.^{61,65} Some adults have received over 1000 mg of atropine in 24 hours (with adequate pralidoxime dosing) without demonstrating antimuscarinic effects,^{61,224} and total doses as high as 11,000 mg during the course of treatment are reported.¹¹³ However, the additional benefit of such extreme doses over more modest doses is unclear. One study reported that much smaller doses of around 1 mg/h were associated with adequate control of muscarinic features after initial atropinization.²¹³

Atropine does not reverse nicotinic effects. Therefore, patients who improve after receiving atropine should ideally be closely monitored in a high dependency setting for impending respiratory failure from delayed NMJ dysfunction. Patients should be clinically examined regularly for proximal muscle weakness (in particular neck flexor weakness); once noted, tidal volume or negative inspiratory force measurements should be made at least every 6 hours to detect impending respiratory failure and allow early instigation of ventilatory support.

When antimuscarinic CNS toxicity becomes evident, yet peripheral cholinergic findings necessitate the administration of more atropine (eg, bradycardia, bronchorrhea, vomiting), glycopyrrolate can be substituted for atropine because its quaternary ammonium structure limits CNS penetration.¹⁷⁷ One randomized clinical trial compared atropine with glycopyrrolate in ICU management of OP poisoning but was too small to detect any difference between regimens.¹⁶ The initial intravenous dose of glycopyrrolate for adults and adolescents is 1 to 2 mg, repeated as needed or in children 0.025 mg/kg up to adult doses. As with atropine, much higher doses of glycopyrrolate may be required to stabilize patients with severe poisonings. Although scopolamine (hyoscine) has been used in place of atropine,^{134,177} it may cause more pronounced CNS effects. If atropine supplies are exhausted during therapy, other antimuscarinic agents like diphenhydramine may be considered.

However, it is not clear that such an approach is required. In a large case series of patients treated by necessity outside of an ICU, atropinization without CNS toxicity could be safely accomplished by slowing atropine infusions whenever absent bowel sounds, confusion, or hyperthermia were detected.⁶⁷ It is therefore unclear whether glycopyrrolate or scopolamine is required for OP poisoning as long as the atropine regimen is adjusted for each patient.

Oximes

Phosphorylated AChE undergoes hydrolytic regeneration at a very slow rate. However, this process can be markedly enhanced by using an oxime such as pralidoxime chloride (2-PAM) or obidoxime (Fig. 113–3).⁸¹ Regeneration of AChE lowers ACh concentrations, improving both muscarinic and nicotinic effects. An immediate rise in RBC AChE activity, presumably paralleling a rise in neuronal AChE activity, can be seen after effective administration of oximes.^{69,211}

As discussed above, phosphorylated AChE becomes aged, and therefore unresponsive to oximes, at different rates according to the chemistry of the OP.⁸¹ Oximes therefore should be given early, within 3 to 4 hours of exposure, after dimethoxy OP poisoning. In contrast, they can still be highly efficacious 48 hours after diethoxy poisoning, with some effects even when given up to several days after exposure. Oximes can also be efficacious weeks after poisoning with a fat soluble OP. Therefore, some AChE may still be undergoing new inhibition for days or weeks after exposure in symptomatic patients, and such inhibition may be reversible by oximes.²³⁰ Case reports support this reasoning by noting dramatic effects in reversing paralysis, weakness, and cholinergic symptoms even after late administration of pralidoxime.^{148–157}

However, the clinical effectiveness of oximes in significant OP insecticide poisoning is still unclear. The first clinical experience with pralidoxime was reported in the late fifties by Namba who treated five patients with occupational parathion poisoning.¹⁵⁷ All patients responded well to around 1 g of pralidoxime IV. As expected from occupational inhalational exposure, none of the patients were very ill. Namba subsequently reported the use of much higher doses of pralidoxime, of 1 to 2 g bolus loading doses followed by 0.5 g/h, in patients with severe parathion poisoning.¹⁵⁵ He also noted that some OPs, including malathion, did not respond well to pralidoxime.¹⁵⁶ These caveats seem to have been lost subsequently, with most textbooks recommending the use of pralidoxime 1 g, followed by a second 1 g bolus after a few hours as necessary for all cases.

Extensive clinical experience of bolus pralidoxime regimens in Asia has led to widespread doubt about the efficacy of oximes.⁷⁵ Asian clinicians have traditionally used 1 g of pralidoxime every 4 to 6 hours for 1 to 3 days, producing high peaks and deep troughs in blood pralidoxime concentration. In a 1992 natural experiment, Sri Lankan doctors reported finding no difference in OP case fatality during a 6-month period when pralidoxime was not available in their hospital, compared to periods when it was available.⁵⁵ They argued that pralidoxime was of little clinical benefit, and since it was expensive, should not be routinely used for treating OP-poisoned patients. European clinician researchers responded that the doses being used in Asia were too low and that higher doses, more akin to Namba's second regimen, were required.¹²² Two further trials from south India reported no effect¹²³ or even harm⁴² from pralidoxime therapy.

All these clinical trials aimed for a plasma oxime concentration of around 4 µg/mL; unfortunately, this target was based on a single study with a single nerve agent in cats²⁰⁴ and should not have been extrapolated to human OP pesticide poisoning in general.⁸¹ In vitro studies with human RBCs suggest that a higher concentration of around 100 µmol (~20 µg/mL) is required for sustained reactivation,^{81,211} resulting in the recommendation from a WHO group that all patients receive a loading dose of at least 30 mg/kg pralidoxime chloride, followed by at least 8 mg/kg/h.¹²¹ A subsequent randomized clinical trial from India showed that very high doses of pralidoxime iodide, a 2 g loading dose followed by 1 g/h, reduced death and length of ventilation in moderately poisoned patients who presented early and were treated in an ICU.¹⁶⁷ However, similar doses of pralidoxime chloride did not reactivate AChE in severe poisoning with dimethoate and other dimethoxy pesticides.⁶⁹

Additionally, another randomized controlled trial from Sri Lanka was unable to demonstrate a benefit from similar high doses of pralidoxime.⁶⁸ This trial compared no pralidoxime chloride with a 2 g bolus over 20 minutes followed by 0.5 g/h for up to 7 days or when atropine was no longer required, in addition to standard therapy. Although the study was stopped earlier than planned, pralidoxime was associated with an adjusted hazard ratio (HR) of 1.69 (95% confidence interval 0.88 to 3.26, *p* = 0.12) for death.

A subsequent Cochrane review concluded that current evidence was insufficient to indicate whether oximes are harmful or beneficial.³¹ It is possible that some of the difference between the outcomes in the two major trials is due to the very high level of supportive care available in India. Despite being less severely poisoned, 66% of Indian patients were intubated at baseline compared to 17% of Sri Lankan patients. This high level of supportive care is not available in rural district hospitals that see the majority of OP-poisoned patients globally.

All the clinical trials included in the Cochrane review assessed pralidoxime salts. Obidoxime⁸¹ has been used in some countries, including Germany^{79,211} and Iran,¹⁴ with apparently beneficial effects. Although use of high dose obidoxime has been associated with liver injury,¹⁴ this does not seem to be the case with doses of 250 mg as a loading dose followed by 750 mg/24 h.⁸¹ The use of newer oximes such as HI-6 and HLo-7 has not yet been reported in pesticide poisoned patients. However, in vitro studies suggest that they will not be highly effective for human AChE inhibited by a range of OP pesticides.²³⁵

Currently, the exact role of oximes is unclear. However, they should be given as soon as possible after exposure to increase the chance of benefit. The difference between Indian and Sri Lankan studies indicates that high quality intensive care is probably required to reduce the risk of serious adverse effects. The duration of use is unclear; ideally, electrophysiological or clinical changes should be monitored to indicate whether oximes offer benefit to the patient.

Some effects of oximes are not well understood. Their quaternary ammonium compound structures are thought to reduce their passage across the blood–brain barrier and prevent CNS effects.²⁰⁷ However, obidoxime has been detected in CSF,⁸¹ and at least one case report describes pralidoxime-induced improvements in mental status and electroencephalograms not attributable to improved ventilation or perfusion.¹³⁹

Benzodiazepines

Animal studies demonstrate that administering benzodiazepines along with oximes in the treatment of poisoning with OP nerve agents or the insecticide dichlorvos can increase survival and decrease the incidence of seizures and neuropathy.^{60,154} Diazepam can also decrease cerebral morphologic damage resulting from OP compound–related seizures.^{24,144} One study suggests that diazepam may help attenuate OP-induced respiratory depression,⁶⁰ postulating that the benzodiazepines attenuate the overstimulation of central respiratory centers caused by OP insecticides. However, seizures have been uncommon in large case series of patients poisoned by OP insecticides,^{69,222} and no clinical studies have yet been performed to determine whether benzodiazepines offer benefit to humans.¹⁴² In the absence of this evidence, benzodiazepines should be used to treat OP-related seizures and agitation and to aid intubation but should not be given routinely to all cases.¹⁴²

Other Treatments

These therapies affect only limited mechanisms involved in OP poisoning. Multiple additional therapies have been tested in animals, but none have been shown to be beneficial in large clinical trials, and none are used widely in clinical practice.^{32,171} Future clinical trials may identify patients for whom they would be beneficial. Treatments that have been proposed include magnesium^{19,163} or clonidine¹⁶⁹ to reduce presynaptic acetylcholine release, fresh frozen plasma as a source of BuChE for scavenging OP pesticides,^{101,173} and sodium bicarbonate.¹⁷⁸

Decontamination

Cutaneous absorption of OP pesticides and carbamates necessitates removal of all clothing as soon as possible after

resuscitation and administration of atropine and oxygen. Medical personnel should avoid self-contamination by wearing neoprene or nitrile gloves. Double-gloving with standard vinyl gloves may be protective. Skin should be triple-washed with water, soap, and water, and rinsed again with water. Although alcohol-based soaps are sometimes recommended to dissolve hydrocarbons,⁸⁵ these products can be difficult to find, and expeditious skin cleansing should be the primary goal. Cutaneous absorption can also result from contact with OP and carbamate compounds in vomitus and diarrhea if the initial exposure was by ingestion. Oily insecticides may be difficult to remove from thick or long hair, even with repeated shampooing, and shaving scalp hair may be necessary. Exposed leather clothing or products should be discarded because decontamination is very difficult once impregnation has occurred.

Military institutions are now experimenting with cholinesterase sponges for cutaneous OP decontamination.⁹³ The sponge consists of a cholinesterase enzyme covalently linked and immobilized in a polyurethane matrix. Reportedly, the sponge is effective in removing OP compounds from skin and surfaces.⁹³

In substantial, potentially life-threatening acute ingestions, if emesis has not occurred and the patient presents within one hour, evacuation of stomach contents by lavage using a nasogastric tube can be done. Because the onset of coma, seizures, and paralysis can be rapid, airway protection is necessary to perform the procedure safely. Although there are data suggesting that activated charcoal (AC) may adsorb some OP insecticides, a study of 1310 Sri Lankan patients with OP or carbamate poisoning found no benefit from the use of multiple dose AC.⁷² Thus, the present recommendation is that patients with anticholinesterase poisoning receive a single dose of 1 g/kg AC.

Health care providers must always maintain caution when coming into contact with stomach contents or other body fluids when managing these cases.¹³⁷ Bystanders have been poisoned by providing mouth-to-mouth resuscitation to a victim of an intentional ingestion of diazinon.¹²⁹ There have also been reports of nosocomial poisoning in ED staff.^{35,89,197} However, in only one paper were BuChE activities tested³⁵ to support the hypothesis of nosocomial poisoning, and none showed any evidence of inhibition. Clinical experience from South Asia suggests that nosocomial poisoning with OP pesticides is unlikely as long as standard universal precautions are followed.¹⁷⁹ It is more likely that the nonspecific illnesses and anxiety reported are due to the solvents co-formulated with the pesticides.¹³⁷ An Australian consensus statement on nosocomial poisoning found little evidence that health care workers were at risk of such poisoning and noted that decontamination should not take place to the detriment of timely resuscitation and medical assessment.¹³⁷

Disposition

After atropinization, patients with cholinesterase inhibitor poisoning should be frequently observed for evidence of (1) deteriorating neurologic function and potential paralysis and (2) need for increases or reductions in atropine dosing.

RBC AChE and BuChE activities can be measured intermittently after the institution of pralidoxime therapy.^{79,81,209,230} Effective oxime therapy will normalize RBC AChE activity but usually does not affect BuChE activity. In the absence of effective oxime therapy, RBC AChE activity may be markedly depressed long after neuronal AChE activity has returned to normal. Therefore, an individual who remains asymptomatic may be discharged home with subnormal cholinesterase activity. BuChE begins to rise when no more OP is left in the body.⁶⁵ A sudden fall in BuChE activity suggests that OP is being redistributed from fat stores. The relevance of a fall in BuChE activity that is not clinically apparent is uncertain. Overall, there is little evidence at present that repeated testing of AChE or BuChE activity improves management and outcome over clinical monitoring alone. Such testing is, however, important for research assessing new interventions.

When available, electromyographic studies to detect signs of motor endplate dysfunction and early AChE inhibition may be a more sensitive method for identifying recurrent cholinergic toxicity.²³ Again, the clinical usefulness of this approach has not yet been studied.

A patient who becomes asymptomatic, not requiring pralidoxime or atropine for 1 to 2 days, may be discharged. Although recurrent cholinergic crises and/or respiratory failure can occur after several days, usually such patients have previously shown clinical signs of some form. Patients should not be allowed to go home wearing clothing that was worn when the poisoning occurred.

Carbamates

The treatment of patients with carbamate poisoning is identical to that of OP compound poisoning, with two exceptions. First, the use of oxime in monomethyl carbamate exposure is controversial, and many providers will not administer it because animal data imply that pralidoxime may increase AChE inactivation in carbaryl poisoning.^{133,136} More recent reports suggest aldicarb poisoning may benefit from oxime therapy¹⁷⁵ and that the dose of pralidoxime may be important in carbaryl poisoning.¹⁴⁷ Comparative human data investigating the use of oximes in carbamate poisonings are currently lacking. Fortunately, because of the rapid hydrolysis of the carbamate-AChE complex, symptoms, including weakness and paralysis, usually resolve within 24 to 48 hours without pralidoxime therapy. However, administering pralidoxime to a poisoned patient in a cholinergic crisis is appropriate when it is not known whether the patient is suffering from OP or carbamate pesticide poisoning. If the poisoning is from a carbamate pesticide, pralidoxime therapy may not be necessary,

but if used will likely not prove detrimental.

Second, significant inhibition of RBC AChE and BuChE by carbamates generally does not last for more than 1 to 2 days, assuming absorption is complete. Patients exposed to carbamates usually have normal cholinesterase activities by the time of discharge. There are no reported cases of recurrent or delayed poisonings following carbamate insecticide poisoning. Therefore, repeating cholinesterase tests after patients are asymptomatic is usually unnecessary. However, of note, complications of poisoning with carbamates—such as aspiration and hypoxic brain injury—can last many days.

SUMMARY

- OP and carbamate insecticides kill hundreds of thousands of people each year.
- Poisoning with these pesticides is not uniform—they differ markedly in their human toxicity, pharmacokinetics, clinical syndrome, and response to therapy.
- Symptoms result from inhibition of AChE and overstimulation of muscarinic and nicotinic receptors in synapses of the autonomic and central nervous systems and at the neuromuscular junction.
- Patients with substantial poisoning present with the cholinergic crisis and show pinpoint pupils, excessive sweating and salivation, and respiratory failure due to bronchospasm, bronchorrhea, loss of central respiratory drive, and dysfunction of neuromuscular junction.
- For severe poisoning, atropine should be administered in doubling doses to attain atropinization before being continued as an infusion at a dose individualized for the patient.
- Patients may develop neuromuscular junction dysfunction that progresses to respiratory failure; such patients often require ventilatory support for weeks.
- Cholinergic features can recur many days after ingestion of very fat-soluble compounds such as fenthion due to redistribution from fat stores.

Acknowledgment

Richard F. Clark, MD, contributed to this chapter in previous editions.

A32 ANTIDOTES IN DEPTH

Atropine

Mary Ann Howland

INTRODUCTION

Atropine is the prototypical antimuscarinic xenobiotic. It is a competitive antagonist at both central and peripheral muscarinic receptors, that is used to treat patients with symptoms following exposures to muscarinic agonists such as pilocarpine, Clitocybe mushrooms, and acetylcholinesterase inhibitors. The latter group includes pesticides, such as carbamate and organic phosphorous compounds, chemical warfare nerve agents, and some xenobiotics used to treat patients with Alzheimer disease, such as donepezil and rivastigmine.

HISTORY

Many plants contain the alkaloids atropine and or scopolamine. One notable example is *Atropa belladonna*, named by Linnaeus after Atropos, the goddess of fate in Greek mythology who could cut short a person's life. Belladonna means beautiful woman in Italian and comes from the practice by Italian women of placing belladonna extract in their eyes to produce aesthetically pleasing dilated pupils.¹⁰ In the early 1800s, atropine was isolated and purified from plants. In the 1860s, Fraser experimented with the dose-response relationship between atropine and physostigmine involving various organs such as the heart and the eye.²⁰ Experiments in the 1940s with cholinesterase inhibitors demonstrated that atropine reversed many of the effects of these xenobiotics and protected animals against doses two to three times the LD₅₀.^{50, 50}

PHARMACOLOGY

Chemistry

Atropine (dl-hyoscyamine), like scopolamine (l-hyoscine), is a tropane alkaloid with a tertiary amine structure that allows central nervous system (CNS) penetration. Quaternary amine antimuscarinics such as glycopyrrolate, ipratropium, tiotropium, methylhomatropine bromide, and methylatropine bromide do not cross the blood-brain barrier into the CNS. Tropane alkaloids are bicyclic nitrogen containing compounds that are naturally found in the plants of the families Solanaceae (eg, deadly nightshade, *Datura*) and Erythroxylaceae (eg, coca) and have a long history of use as poisons and medicinals. Only l-hyoscyamine is active and found in nature. The process of isolation results in racemization and forms dl-hyoscyamine.

Mechanism of Action

Cholinergic receptors consist of muscarinic and nicotinic subtypes. Muscarinic receptors are coupled to G proteins and either inhibit adenylyl cyclase (M₂, M₄) or increase phospholipase C (M₁, M₃, M₅). Muscarinic receptors are widely distributed throughout the peripheral and central nervous systems.²³

The competitive blockade of muscarinic receptors in normal individuals results in dose-dependent clinical effects that

vary by organ system based on the degree of endogenous parasympathetic tone.^{10,23} In adults, low doses (0.5 mg) of atropine sometimes causes a paradoxical bradycardia of about 4 to 8 beats per minute, not evident with rapid IV administration. Higher doses of atropine (2 mg) produce noticeable dryness of the mouth and sweat glands, feeling of warmth, flushing, tachycardia, reactive dilated pupils, blurred near vision, drowsiness, postural hypotension, and urinary hesitation. At higher doses (3 to 5 mg) of atropine, all the aforementioned symptoms are exaggerated, with escalating degrees of hyperthermia, tachycardia, drowsiness, difficulty voiding, prolonged gastrointestinal transit time, and decreased peristalsis. Doses of greater than or equal to 10 mg of atropine produce incapacitation with hot, dry, flushed skin, dilated pupils, blurred vision, very dry mouth, tachycardia, urinary retention, constipation, increased drowsiness or disorientation, hallucinations, stereotypical movements, bursts of laughter, delirium, and finally, coma, and rarely death.^{10,22}

The paradoxical bradycardia produced at low doses of atropine is thought to be a consequence of the inhibition of peripheral M₁ presynaptic postganglionic parasympathetic neurons. Stimulation of these receptors by acetylcholine inhibits the further release of acetylcholine, and atropine interferes with this negative feedback.^{10,48} Not all studies, however, have shown this paradoxical decrease in heart rate.²⁷

Centrally acting muscarinic antagonists include atropine, scopolamine, and homatropine. Glycopyrrolate, ipratropium, and tiotropium act peripherally. Scopolamine is approximately 10 times more potent than atropine.³¹ Homatropine is approximately one-tenth as potent as atropine, depending on the measured outcome and route of administration.²⁹

Cholinesterase inhibitors prevent the breakdown of acetylcholine by acetylcholinesterase, thereby increasing the amount of acetylcholine available to stimulate cholinergic receptors at both muscarinic and nicotinic subtypes, although the degree of effect varies widely among the class. Atropine is a competitive antagonist of acetylcholine only at muscarinic receptors and not nicotinic receptors.¹³

Miosis from the topical instillation of a cholinesterase inhibitor into the eye will not be reversed by the systemic administration of atropine.²² The systemic administration of 354 mg of atropine made one patient floridly anticholinergic but did not counteract the ophthalmic effects of a previously instilled topical cholinesterase inhibitor.²²

Pharmacokinetics and Pharmacodynamics

Atropine is absorbed rapidly from most routes of administration including inhalation, oral, and intramuscular (IM).³ Ingestion of 1 mg of atropine produces maximal effects on heart rate and on salivary secretions in 1 and 3 hours, respectively. The duration of action may last from 12 to 24 hours, depending on the dose.

The distribution half-life of atropine following intravenous (IV) administration is approximately one minute. The apparent volume of distribution (V_d) is about 2 to 2.6 L/kg.²⁹ As a result of the rapid distribution, 10 minutes after IV administration less than 5% of the dose remains in the serum. The serum concentrations of atropine are similar at 1 hour following either 1 mg IV or IM in adults.^{3,7} The elimination half-life is 6.5 hours.⁴¹

Following IM administration of 0.02 mg/kg in adults, the absorption rate and elimination rates are comparable for the racemic dl-hyoscyamine and the active l-hyoscyamine at 8 minutes and 2.5 hours, respectively. The mean peak serum concentration and the area under the curve (AUC) are higher for the racemic mixture indicating a stereochemical difference in pharmacokinetics.²⁹ Renal elimination accounts for 34% to 57% of the excretion of the dose, and the majority of renal elimination occurs within 6 hours.³ Serum concentrations of l-hyoscyamine correlate with effects on heart rate and the antisialagogue effects. Serum concentrations below 0.5 µg/L may cause bradycardia in adults, whereas higher concentrations cause tachycardia.²⁹

A study of intraosseous (IO) administration in minipigs demonstrated a pharmacokinetic profile similar to IV atropine.³⁵ The time to maximum concentration following a dose of 0.25 mg/kg was 2 minutes with both IV and IO injection, compared to 3.5 minutes for IM injection.

Atropine autoinjectors are now given to first responders for use during chemical terrorist attacks. The administration of 2 mg of atropine by autoinjector was compared with 2 mg administered by conventional needle and syringe into the deltoid of six adult subjects.⁴⁶ The onset of tachycardia and the time to maximal increase in heart rate occurred sooner with the autoinjector (16 minutes versus 23 minutes, and 34 minutes versus 41 minutes, respectively). An analysis of radiographs of contrast material injected by autoinjector or conventional IM administration into the leg of a dog demonstrated that the autoinjector appeared to “spray” the material into a larger tissue area, accounting for a faster rate of absorption.⁴⁶

Ophthalmic instillation of atropine causes cyclopegia and mydriasis by blocking the M₃ muscarinic receptor on the iris sphincter muscle.³⁴ The peak mydriatic effect occurs within 30 to 40 minutes and persists for 7 to 10 days. In contrast, the effects of topical homatropine on the eye occur sooner than topical atropine (10–30 minutes for mydriasis and 30–90 minutes for cyclopegia) and are shorter in duration (6–48 hours).

The effects on pupillary dilation after systemic atropine administration depend on the dose and route of administration. An IM dose of 0.01 mg/kg into the thigh of healthy adults produced no change in pupil size,¹⁴ while subcutaneous administration into the upper arm of doses of 0.5 mg, 1 mg, and 2 mg per 70 kg person produced a dose dependent increase

in pupil size. An oral dose of 0.02 mg/kg also produced pupillary dilation.^{12,27}

An investigation of the bioavailability of atropine eye drops in healthy adults revealed approximately a 65% systemic absorption, but with a wide individual variability.²⁸ The time to maximum serum concentration was 30 minutes, and the apparent elimination half-life was 2.5 hours.

The pharmacokinetics of three inhaled doses of atropine from a metered dose nebulizer was compared with 2 mg of IM atropine in healthy adults.²⁴ Peak concentrations were comparable for the 2 mg inhaled and 2 mg IM atropine doses. The time to peak concentration following inhalation averaged 1.3 hours. A novel nanoatropine dry powder inhaler is being evaluated to rapidly achieve blood concentrations of atropine in the hopes of circumventing IM administration.²

ROLE IN ORGANIC PHOSPHOROUS AND CARBAMATE TOXICITY

One of the earliest descriptions of the effectiveness of atropine in parathion and tetraethylpyrophosphate insecticide poisoning was published in 1955.²¹ Atropine improved survival when administered early and continued with adequate maintenance doses, intubation, and ventilation. Parathion and tetraethylpyrophosphate insecticide exposure led to heart block and bronchoconstriction in dogs, whereas humans were more likely to develop a relative bradycardia. Humans were more likely to die from respiratory causes resulting from central apnea, diaphragmatic weakness, and bronchorrhea.

In 1971, a landmark case series and review of organic phosphorus compound (OP) insecticide poisonings was published. Included was a table classifying the severity of poisoning along with treatment protocols for each level of severity.³⁶ This regimen served as the foundation of treatment regimens (atropine and pralidoxime) for many years.

In the 1930s and 1940s, the Germans synthesized OP insecticides (acetylcholinesterase inhibitors) that were further developed as chemical warfare nerve agents ([Chap. 132](#)).⁴⁵ Although these xenobiotics inhibit acetylcholinesterase in a manner similar to traditional OP insecticides, these so-called “nerve agents” also affect other cholinesterases, and at high doses directly affect nicotinic and muscarinic receptors. Atropine was chosen in the late 1940s as the standard antidote for these nerve agents. The dose of atropine needed to antagonize these nerve agents is much less than that needed to effectively antagonize traditional OP insecticides, largely because of differences in pharmacokinetics. The benefits of adding pralidoxime to atropine were noted in the 1950s, and in the 1960s, pralidoxime was established as a standard antidote in addition to atropine for these xenobiotics ([Antidotes in Depth: A33](#)).

ADVERSE EFFECTS AND SAFETY ISSUES

When atropine is used in the absence of a xenobiotic that increases or mimics acetylcholine, adverse effects begin at 0.5 mg IV in the adult and include dry mouth and decreased sweat. However, in the presence of muscarinics or anticholinesterases, these effects may not occur until many milligrams of atropine are administered.

Intravenous doses of greater than 10 mg of atropine and oral doses of 500 to 1000 mg have been administered with full recovery. Deaths from atropine use are usually correlated with hyperthermia.

An unintentional atropine dose of one thousand milligrams orally resulted in typical manifestations of anticholinergic poisoning that began within a short time and lasted 4 days.¹ In 2 hours the patient went from feeling hot and flushed with blurred vision to stupor. Over the ensuing 24 hours he became tachycardic, hyperthermic, and comatose with dilated, nonreactive pupils and shallow respirations. By 40 hours he started to respond to his name and his temperature had normalized, but he had dry mucous membranes with dilated and nonreactive pupils. He went from coma to restlessness, hallucinations, and paranoia. At 4 days he regained a normal mental status with amnesia for the previous 4 days.

A survey of pediatric emergency departments in Israel reported on 240 children who were unintentionally injected by atropine autoinjections or autoinjector systems, triggering unintended administration, self administration, needle injury, or delivery to an unintended site during the Persian Gulf crisis.⁴ Half of the children developed systemic effects that correlated with the doses of atropine administered. Eight percent of effects were serious, but there were no seizures or deaths.

Systemic atropine toxicity may occur when too large a dose of atropine, scopolamine, or homatropine is instilled in the eye, especially in children.³⁸ Excessive absorption from other routes of administration such as rectal or inhalation would also be expected to result in toxicity.⁴⁴ In the event of an atropine overdose, physostigmine, a reversible, CNS active, cholinesterase inhibitor, is the antidote of choice ([Antidotes in Depth: A9](#)).³⁷ Schizophrenic patients in the 1950s were often given atropine as a treatment. Within 15 to 20 minutes of getting 32 to 212 mg of IM atropine, patients become restless and often confused. This progressed to muscular incoordination, ataxia, weakness, and garbled speech.¹⁹ The patients then progressed to disorientation with illusions, visual hallucinations, and delirium, to coma. The coma often lasted for 4 to 6 hours, and then patients recovered in a manner that in some respects is the reverse of poisoning. Regardless of the dose of atropine required to induce the coma, physostigmine 4 mg IM completely reversed the toxicity within 20 minutes, although the reversal only lasted for 30 to 45 minutes.^{19,37}

Other precautions or contraindications to consider when administering atropine include those associated with all antimuscarinics and include narrow angle closure glaucoma, obstructive uropathy, gastroparesis, pylorospasm, relaxation of the lower esophageal sphincter, and myasthenia gravis. Of course these complications must be weighed against the possible life-threatening nature of OP, carbamate, and chemical nerve agent poisoning.

PREGNANCY AND LACTATION

Atropine is classified by the Food and Drug Administration (FDA) as pregnancy category C. Atropine crosses the placenta and may cause tachycardia in the fetus near term. Human data suggest low risk, and atropine should be used when indicated.^{9,47} The American Academy of Pediatrics classifies atropine to be as compatible with breast-feeding.⁹

DOSING AND ADMINISTRATION

The dosage regimen of atropine for pesticide poisoning in adults has never been evaluated in a randomized, controlled trial, and there is considerable variation in recommendations in the literature.¹⁶ A prospective, observational study suggested that a dose doubling, titrated protocol provided equal efficacy with less atropine toxicity compared with a less preplanned ad hoc dosing protocol.⁴⁰ Experience suggested that atropine should be initiated in adults in doses of 1 to 2 mg IV for mild to moderate poisoning and 3 to 5 mg IV for severe poisoning with unconsciousness.³⁶ This dose can be doubled every 3 to 5 minutes until improvement has begun, at which time dose doubling can stop and similar or smaller doses can be used.^{17,42} We believe that the most important end point for adequate atropinization is the resolution of bronchorrhea and the reversal of the muscarinic toxic syndrome. However, it is important not to confuse abnormal focal auscultatory sounds associated with pulmonary aspiration with those of extensive bronchorrhea.^{17,42} Some authors suggest clear lungs, heart rate greater than or equal to 80 beats/min, and systolic blood pressure exceeding 80 mm Hg as the most important goals of therapy, and dry axillae and wider than pinpoint pupils as additional goals.¹⁸ Once these end points are achieved, a maintenance dose of atropine needs to be started. One group suggests administering 10% to 20% of the loading dose as an IV infusion every hour as a starting point with meticulous, frequent reevaluation and titration.^{16,17} Atropine can be diluted in 0.9% sodium chloride, with rates of 0.5 to 1.5 mg/h of atropine commonly used.⁴⁰ For example, if a patient received atropine 2 mg IV, then 4 mg in 5 minutes, and 8 mg in 5 minutes, when improvement in bronchorrhea is noticeable, the total loading dose to initial control would be 14 mg in 10 minutes. The initial IV infusion dose of atropine would be 1.4 mg/h. This could be achieved by mixing 10 mg of atropine in 100 mL of 0.9% sodium chloride to make a concentration of 0.1 mg/mL and infusing it at 14 mL (1.4 mg)/h. If too much atropine is administered, the patient demonstrates classic signs of peripheral and central anticholinergic toxicity as described above.

The IV/IO starting dose of atropine in children is 0.02 mg/kg up to the adult dose.^{39,42,49} A continuous infusion of 0.025 mg/kg/h was successfully used in a 2 year-old child following a fenthion poisoning.⁸ Although a minimum dose of 0.1 mg has been advocated, this dose would be toxic to infants <5 kg and is not recommended.⁶

In the event that a person is exposed to a chemical warfare nerve agent, atropine should be administered in a dosage suitable for both the severity of the poisoning and the age of the patient. In a conscious adult with mild to moderate cholinergic effects, 2 mg of atropine IV or IM should be administered every 5 to 10 minutes until shortness of breath improves and drying of secretions occurs.⁴⁵ One adult autoinjector of atropine for IM administration, Mark 1 Nerve Agent Antidote Kit (NAAK), contains 2 mg of atropine, and therefore multiple injectors may be required. Total doses of 2 to 4 mg of atropine are usually all that is needed, which is much lower than the dose for most OP pesticide exposures. Patients who are unconscious or apneic require higher total doses, with 5 to 15 mg usually sufficing.⁴⁵

The appropriate total Mark 1 autoinjector doses of atropine for children depend on age and weight.^{25,32} For ages 3 to 7 (13–25 kg), one autoinjector (2 mg) of atropine and one autoinjector of pralidoxime (600 mg) should be administered, resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For ages 8 to 14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered, resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For patients older than 14 years of age, three autoinjectors of atropine and pralidoxime should be administered, resulting in a projected dose of atropine of less than 0.11 mg/kg. In an emergency for children younger than 3 years of age, a risk-to-benefit analysis would suggest injecting one autoinjector of atropine and one of pralidoxime. If time permits and only one autoinjector is available for use, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.²⁶ Some experts recommend that children under the age of one year be administered one pediatric atropine autoinjector (0.5 mg), such as AtroPen (Meridian Medical Technologies, Inc.), if available, and children over the age of one year be administered the Mark 1 autoinjector as described above.

When IV administration is not feasible, atropine may also be administered IO at the standard IV dose. However, the dose for endotracheal administration in adults should be two to two-and-a-half times the IV dose, diluted in 5 to 10 mL of 0.9% sodium chloride solution or sterile water. For children, the 2010 American Heart Association guidelines for

pediatric advanced life support recommend 0.04 to 0.06 mg/kg in a child endotracheally, followed by a flush of 5 mL of 0.9% sodium chloride solution and then five manual ventilations to enhance absorption.³⁹

FORMULATION AND ACQUISITION

Atropine sulfate injection is available in many different strengths, with the following concentrations in each 1 mL vial or ampule: 50 µg, 300 µg, 400 µg, 500 µg, 800 µg, and 1 mg. Atropine sulfate is also available in prefilled 5 mL or 10 mL syringes with a concentration of 0.1 mg/mL for adults and in 5 mL syringes with a concentration of 0.05 mg/mL for pediatrics.

The AtroPen Auto-Injector is a prefilled syringe designed for IM injection by an autoinjector into the outer thigh.⁵ It is available in four strengths: 0.25 mg, 0.5 mg (blue label), 1 mg (dark red label), and 2 mg (green label).

Atropine is also packaged in a kit designed for IM injection with a second autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg benzyl alcohol and 22.5 mg glycine. The pralidoxime injector is accompanied by an atropine autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This particular combination kit is called a “Mark 1 Nerve Agent Antidote Kit” and is designed for IM use in case of a nerve agent attack. The needles are 0.8 inches in length.³³ The Mark 1 NAAK has recently been replaced by the DuoDote Autoinjector System and the analagous, military designated antidote treatment nerve agent, autoinjector (ATNAA), which use technology that sequentially administers 2.1 mg in 0.7 mL atropine followed by 600 mg in 2 mL pralidoxime chloride IM through the same syringe. The 23 gauge needle is 0.8 inches in length.

Atropine is available orally in 300 µg, 400 µg, and 600 µg tablets.

In case of a shortage during an emergency, large quantities of atropine syringes can be compounded by a pharmacist from atropine powder utilizing standard syringe batching system.³⁰ In vitro evidence suggests that outdated atropine retains its potency and that an extemporaneously prepared atropine solution from powder is stable for at least 3 days.^{15,43} Other sources of atropine to consider in an emergency during a shortage would be atropine eye drops, which come as a 1% concentration (10 mg/mL). Homatropine, available as eye drops in a 2% or 5% concentration, compared favorably with atropine in preventing lethality when administered IM in a pretreatment rodent model using dichlorvos. In this experimental model, homatropine appeared to be half as potent as atropine.¹¹ Atropine is maintained as part of the Strategic National Stockpile (SNS) for formulary in repositories in numerous locations throughout the United States.

SUMMARY

- Atropine has many clinical uses as a competitive antagonist at both central and peripheral muscarinic receptor sites.
- The use of atropine is extensive for patients with bradycardias, in advanced cardiac life support, and in those exposed to acetylcholinesterase inhibitors in the workplace, in the home, and potentially on the battlefield.
- Atropine should be dosed to the resolution of bronchorrhea caused by the muscarinic toxidrome using a dose-titrated doubling protocol.

A33 ANTIDOTES IN DEPTH

Pralidoxime

Mary Ann Howland

INTRODUCTION

Pralidoxime chloride (2-PAM) is the only cholinesterase-reactivating xenobiotic currently available in the United States. It is used concomitantly with atropine in the management of patients poisoned by organic phosphorus (OP) compounds. Administration should be initiated as soon as possible after exposure, but can be effective even days after an exposure and therefore should be administered to all symptomatic patients independent of delay. Continuous infusion is preferable to intermittent administration for patients with serious toxicity, and a prolonged therapeutic course may be required.

HISTORY

It was recognized in the 1950s that certain phosphate esters were potent and irreversible inhibitors of acetylcholinesterase (AChE).^{84,85} Identification of an anionic site on AChE led to the theory that a compound could be developed that would bind to this site and remove the phosphate ester, thereby reactivating AChE. A few hydroxylamine derivatives were studied and led to the design of pralidoxime.⁸⁵

PHARMACOLOGY

Chemistry

Pralidoxime chloride is a quaternary pyridinium oxime with a molecular weight of 173 Da. The chloride salt exhibits excellent water solubility and physiologic compatibility. Pralidoxime iodide has a molecular weight of 264 Da, is less water soluble, and can potentially induce iodism.³

Related Xenobiotics

Organic phosphorous pesticides and nerve agents both cross the CNS. A disadvantage of pralidoxime is that in vivo rat studies it demonstrates only a 10% CNS penetration.⁶⁶ Strategies to enhance the penetration of oximes across the blood–brain barrier (BBB) include enhancing lipophilicity by adding a fluorine atom into the ring structure, designing a glucose-oxime drug which could use facilitated glucose transporters to cross the BBB, designing a prodrug of pralidoxime that could be oxidized to the active drug once it had crossed the BBB, conjugating the oxime with amidine, and by using a targeted nanoparticle drug delivery system.⁵⁰

Obidoxime (Toxogonin, LuH-6) is an oxime used outside the United States that contains two active sites per molecule and is considered by some to be more effective than pralidoxime.^{23,24,88} An in vitro study using human erythrocyte AChE supported the superiority of obidoxime to pralidoxime in reactivating AChE inhibited by the dimethyl phosphoryl (malaaxon, mevinphos) and diethyl phosphoryl OP compounds (paraoxon). On a molar basis, obidoxime is approximately 10 to 20 times more effective in reactivating AChE than pralidoxime.⁸⁸ A potential disadvantage is the concern that the phosphorylobidoxime generated from the reactivation of AChE by obidoxime could reinhibit AChE if not metabolized by a plasma enzyme similar or identical to human paraoxonase 1 (PON1). PON1 exhibits polymorphism²¹ and one in 20 patients may not be able to metabolize this phosphorylobidoxime compound. Phosphorylpralidoxime is unstable and does not accumulate. A molecular docking simulation study demonstrated that pralidoxime had better positioning at the oxyanion hole compared to obidoxime, allowing better reactivation of methamidophos inhibited AChE.⁴³ The H series of oximes (named after Hagedorn; HI-6, HLo-7) were developed to act against the chemical warfare nerve agents⁶ (Chap. 132). These oximes have superior effectiveness against sarin, VX, and certain types of newer pesticides (eg, methyl-fluorophosphonylcholines).^{3,11,37,40,44,65,88,89} Unfortunately, they are less efficacious for traditional OP insecticide poisoning, and their toxicity profile is inadequately defined.^{11,37,40,44,65,88,89} In addition to reactivating AChEs, the Hagedorn oximes demonstrate direct central and peripheral anticholinergic effects at supratherapeutic concentrations.⁶⁵

Mechanism of Action

Organic phosphorus compounds are powerful inhibitors of carboxylic esterase enzymes, including acetylcholinesterase (AChE; true cholinesterase, found in red blood cells, nervous tissue, and skeletal muscle) and plasma cholinesterase or butyrylcholinesterase (found in plasma, liver, heart, pancreas, and brain).⁵⁵ The OP binds firmly to the serine-containing esteratic site on the enzyme, inactivating it by phosphorylation (Fig. 113–3).^{36,56,76} This reaction results in the accumulation of acetylcholine at muscarinic and nicotinic synapses in the peripheral and central nervous systems, leading to the clinical manifestations of OP poisoning. Following phosphorylation, the enzyme is inactivated and can undergo one of three processes; endogenous hydrolysis of the phosphorylated enzyme, reactivation by a strong nucleophile, such as pralidoxime, and aging, which involves biochemical changes that stabilize the inactivated phosphorylated molecule and render it incapable of reactivation by oximes.

Endogenous hydrolysis of the bond between the enzyme and the OP is generally extremely slow and is considered insignificant. This is in contrast to the rapid hydrolysis of the related bond between the enzyme and many carbamates. The positively charged quaternary nitrogen of pralidoxime is attracted to the negatively charged anionic site on the phosphorylated enzyme, bringing it in close proximity to the phosphorous moiety (Fig. 113–3). Pralidoxime then exerts a nucleophilic attack on the phosphate moiety, successfully releasing it from the AChE enzyme.⁸³ This action liberates the enzyme to a variable extent depending on the OP in question and restores enzymatic function.⁴⁵ Diethylorganophosphates (eg, parathion, chlorpyrifos, phorate) take days to age in comparison to 12 hours for dimethylorganophosphates (eg, dimethoate, dichlorvos, monocrotophos).^{17,25}

Pralidoxime is important at nicotinic sites where atropine is ineffective, most often typically improving muscle strength within 10 to 40 minutes after administration.^{56,76} This effect is vital to maintaining the muscles of respiration. Pralidoxime is also synergistic with atropine; it liberates cholinesterase enzyme so that additional acetylcholine can be metabolized while atropine inhibits the effects of acetylcholine at cholinergic receptors. This suggests that pralidoxime should always be used with atropine.^{24,56} Some OP compounds respond much better to pralidoxime than others, depending on the affinity of pralidoxime for the particular type of phosphorylated enzyme, its reactivating ability, concentrations of both the oxime and the OP, aging, and OP redistribution from a depot site such as fat.^{23,88}

The central nervous system (CNS) benefits of pralidoxime are controversial, as the molecule is a quaternary nitrogen compound and not expected to cross the blood–brain barrier.^{47,56} A rat experiment using a microdialysis technique demonstrated only 10% CNS penetration of pralidoxime.⁶⁶ Following exposure to IV fenitrothion, IV administration of pralidoxime in rats failed to improve survival or to reactivate brain cholinesterase, whereas with direct brain instillation pralidoxime partially restored brain cholinesterase and eliminated fatalities.⁷⁹ Clinical observations, however, have certainly suggested a CNS action of pralidoxime with a prompt return of consciousness reported in some cases.^{55,56,63,83} A 3 year-old child who was comatose from parathion was given 500 mg of 2-PAM IV over 15 minutes with continuous electroencephalographic (EEG) monitoring. Within 2 minutes there was a dramatic response on the EEG, followed rapidly by normalization of consciousness.³⁵

Early work with feline models led to a proposal that a serum concentration of greater than or equal to 4 µg/mL was a desired therapeutic concentration for pralidoxime.⁷⁵ However, more recent in vitro work with human erythrocytes and a mouse hemidiaphragm model suggests that higher serum concentrations are actually needed.⁸⁸ Twenty percent reactivation was achieved in 5 minutes with serum concentrations of 10 µg/mL.⁸⁸ A simulation and analysis suggests that serum concentrations between 10 and 15 µg/mL (50–100 µmol/L) are necessary for optimal treatment of severely poisoned patients.^{21,90} These recommendations await validation in poisoned patients. Serum concentrations are not available in a timely manner, but may help in the design of future pralidoxime dosing protocols.

Organic phosphorous compounds inhibit butyrylcholinesterase (plasma cholinesterase) and AChE to different extents.¹⁸ If performed correctly, butyrylcholinesterase may act as a surrogate marker for OP or carbamate elimination from the body.³⁸ Likewise, the reactivation of butyrylcholinesterase by pralidoxime is dependent on the concentration of pralidoxime and often has a flat dose response. For example, in an in vitro model of human blood taken from healthy volunteers and treated with paraoxon, pralidoxime was able to reactivate 1.3% and 18.1% of AChE at pralidoxime concentrations of 10 µmol and 100 µmol, respectively, compared with only 1% and 5.5% of butyrylcholinesterase with 10 and 100 µmol concentrations of pralidoxime.³⁵ Unless the effect of the specific OP on butyrylcholinesterase is known, there is no role for following serial butyrylcholinesterase concentrations.

In contrast to the usefulness of pralidoxime in the management of the cholinergic syndrome, current understanding of the pathophysiology of the intermediate syndrome is inadequate to determine whether pralidoxime can prevent the development of the syndrome (Chap. 113).⁷⁴ However, if cholinergic receptor desensitization is responsible for the cause of the muscle weakness, then pralidoxime would be unlikely to prevent the syndrome, especially after large intentional ingestions.¹² Additionally, certain OP pesticides may lead to the development of delayed onset neurotoxicity, which involves inhibition of neurotoxic esterases that cannot be prevented or treated by pralidoxime.^{19,48}

Pharmacokinetics and Pharmacodynamics

Pralidoxime chloride pharmacokinetics are characterized by a two-compartment model. Pharmacokinetics values vary depending on whether calculations are determined in healthy volunteers or poisoned patients. The volume of distribution (Vd) is larger in poisoned patients and most likely accounts for the prolonged elimination phase.²¹

In volunteers, the Vd is about 0.8 L/kg and the $t_{1/2}$ is 75 minutes.^{33,61,72} Pralidoxime is renally excreted, and within 12 hours, 80% of the dose is recovered unchanged in the urine.^{34,71}

A dose of 10 mg/kg of pralidoxime administered intramuscularly (IM) to volunteers results in peak serum concentrations of 6 µg/mL (reached 5–15 minutes after IM injection) and a half-life of approximately 75 minutes.⁷¹ Following a standard 30 minute IV infusion dose of 1 g of pralidoxime in a 70 kg man, the serum concentration fell to less than 4 µg/mL (no longer thought to be considered a goal serum concentration) at 1.5 hours. In a simulated model, a continuous infusion of 500 mg/h of pralidoxime led to a concentration greater than 4 µg/mL after 15 minutes, which could be maintained throughout the infusion.⁷⁷ In a human volunteer study, an IV loading dose of 4 mg/kg over 15 minutes followed by 3.2 mg/kg/h for a total of 4 hours maintained serum pralidoxime concentrations greater than 4 µg/mL for 4 hours. The approximately same total dose, 16 mg/kg, administered over 30 minutes only maintained those concentrations for 2 hours.⁴⁹ In poisoned patients receiving continuous infusions of pralidoxime as opposed to intermittent infusions, both the Vd and the $t_{1/2}$ are increased.⁷⁸ A Vd of 2.77 L/kg, an elimination $t_{1/2}$ of 3.44 hours, and a clearance of 0.57 L/kg/h were reported in poisoned adults given a mean loading dose of 4.4 mg/kg followed by an infusion of 2.14 mg/kg/h.⁸³ In poisoned children and adolescents, the Vd varied with severity of poisoning from 8.8 L/kg in the severely poisoned patients to 2.8 L/kg in moderately poisoned patients.⁶⁸ After a mean loading dose of 29 mg/kg followed by a continuous infusion of about 14 mg/kg/h, a steady-state serum concentration of 22 µg/mL, a $t_{1/2}$ of 3.6 hours, and a clearance of 0.88 L/kg/h were calculated.⁶⁸

Oral administration of salts of pralidoxime (not used clinically because of OP poisoning–induced vomiting) demonstrated a peak concentration at 2 to 3 hours, a $t_{1/2}$ of 1.7 hours, and an average urine recovery of 27% of unchanged

pralidoxime in humans.³⁹ Oral administration demonstrated clinical efficacy in a mice model.⁸

Autoinjector administration of 600 mg of pralidoxime chloride in an adult man (9 mg/kg) produced a concentration above 4 µg/mL at 7 to 16 minutes, a maximum serum concentration of 6.5 µg/mL at about 28 minutes, and a $t_{1/2}$ of 2 hours.^{61,70} Using traditional needle and syringe IM administration requires a longer time to achieve comparable serum concentrations. The autoinjectors more widely disperse the medication in the tissues resulting in faster absorption.^{64,72}

ROLE IN ORGANIC PHOSPHORUS COMPOUND TOXICITY: EFFICACY RELATED TO TIME OF ADMINISTRATION AFTER POISONING

The sooner after exposure to an OP, the more likely pralidoxime is to be effective. Timely administration reduces the likelihood that aging of the OP–AChE complex has occurred and is completed. However, there is no absolute time limitation on reactivation function, as long as the patient remains symptomatic.

Early in vitro evidence suggested that the successful use of cholinesterase reactivators depended on administration within 24 to 48 hours of exposure to the OPs; afterward, the acetylcholinesterases would be irreversibly inactivated.^{4,14,31,32,67} The 48 hour limit was derived from in vitro experiments using a small number of tightly bound compounds and reactivators and data from plasma cholinesterase enzyme activity, which is now recognized to be relatively resistant to oxime-nucleophilic attack. These early data were accepted without consideration of their relevance to human systems, the use of newer and less tightly bound OP compounds, temperature and pH variation, blood flow, fat solubility, active metabolites, and species specificity. Fat soluble OP compounds redistribute from fat stores over time and can continue to newly inhibit AChE for days.

An in vitro experiment assessed the effect of aging on the ability of pralidoxime to regenerate rat erythrocyte and brain cholinesterases using three different OP compounds.⁸⁰ The rate of reactivation of erythrocyte and brain cholinesterases was significantly decreased over time for fenitrothion and methyl parathion, with no reactivation occurring at 48 hours. This is partly because dimethylated (dimethyl, dimethoxy) OP pesticides age more quickly than diethylphosphorylated pesticides.¹⁹ In contrast, a very high reactivation rate for ethyl parathion was still apparent at 48 hours. Thus the structure of the OP compound is important in the rates of aging and reactivation with pralidoxime. Fenitrothion and methyl parathion are both O,O-dimethyl OP compounds as is dimethoate, whereas ethyl parathion is an O,O-diethyl OP compound.⁸⁰ Other studies also suggest that pralidoxime remains effective for more than 48 hours following exposure.^{2,5,8,13,16,19,21,53,62,82}

ROLE IN ORGANIC PHOSPHOROUS COMPOUND TOXICITY: HUMAN TRIALS

There are four randomized clinical trials examining the efficacy of pralidoxime for the management of OP poisoning. Two of these trials were done in the 1990s in India using doses of pralidoxime now considered to be inadequate.¹⁹ Neither study demonstrated a benefit for pralidoxime and, in fact, suggested an increase in mortality in patients receiving the higher but still inadequate dose of pralidoxime. Other criticisms include a delay in administration and an inadequate duration of treatment. The third clinical trial included 200 patients in India who were moderately to severely poisoned with an OP pesticide.⁵⁸ All patients received a 2 g loading dose of pralidoxime iodide over 30 minutes before being randomized to receive 1 g over 1 hour every 4 hours for 48 hours or a continuous infusion of 1 g/h for 48 hours. Beyond 48 hours, all patients received 1 g every 4 hours until no longer ventilator dependent. In the continuous pralidoxime infusion arm, the authors demonstrated reduced atropine requirements, a smaller number of patients requiring intubation, fewer days of intubation, and a reduction in mortality from 8% to 1%. It should be noted that the iodide salt of pralidoxime was used and would equate to about 650 mg/h of the chloride salt.²² Even though the majority of the patients by history ingested dimethoate, a dimethoxy compound with high lethality and rapid aging, the time to admission and administration of pralidoxime was very short with a median time of 2 hours. Criticisms of the study include a lack of blinding, no measurement of AChE or pesticide concentrations, and no objective monitoring of neuromuscular function.²² In contrast, the most recent trial performed in Sri Lanka was unable to demonstrate a beneficial effect of pralidoxime in 121 patients compared to 114 patients treated with placebo.²⁰ There was no difference in mortality between groups, although pralidoxime effectively reactivated red cell AChE inhibited by diethyl OP insecticides. It also reactivated red cell AChE inhibited by dimethyl OP insecticides, but less so, as expected. In comparison to the third study,⁵⁸ these patients arrived later (4.4 versus 2 hours), and the extent of supportive care was inferior. The exact reasons for these disparate results are unclear.

ROLE IN CARBAMATE TOXICITY

Acetylcholinesterases inactivated by most carbamates spontaneously reactivate with half-lives of 1 to 2 hours, and typical clinical recovery occurs in several hours. However, in severe cases, cholinergic findings may persist for 24 hours.^{10,28} Pralidoxime is rarely indicated for carbamate poisoning, but it is not contraindicated as previously suggested. This erroneous conclusion was based solely on data regarding a single carbamate, carbaryl, and inappropriately applied to all carbamates. Pralidoxime decreased the rate of carbamylation of 16 insecticidal carbamates, though it modestly increased the rates for three, one of which was carbaryl.¹⁵ In another experiment, pralidoxime had no effect on the reactivation of human erythrocyte AChE carbamylated by aldicarb, methomyl, and carbaryl.⁴¹ Furthermore, animal studies demonstrated the beneficial effects of pralidoxime in decreasing the lethality of several carbamate insecticides,^{57,73} though worsened the toxicity of carbaryl. It was suggested that this is possibly because the carbamate-oxime complex may actually be a more potent cholinesterase inhibitor than carbaryl alone.^{28,57,73} However, even in the presence of carbaryl, the combination of atropine plus an oxime, a more clinically relevant situation, resulted in survival data comparable to that of atropine alone.²⁸ Previous animal data may also be confounded by the use of excessive doses of pralidoxime.⁵¹ This evidence suggests that pralidoxime is not usually a necessary adjunct to atropine for a patient with a pure carbamate overdose. However, there are cases reports, particularly with aldicarb, where pralidoxime appears to improve outcome.¹⁰ Thus pralidoxime should never be withheld in a seriously poisoned patient out of concern that a cholinergic xenobiotic may be a carbamate.⁴¹ Pralidoxime should be used in conjunction with atropine and rarely as the sole therapy in OP or carbamate poisoning.

ADVERSE EFFECTS AND SAFETY ISSUES

At therapeutic doses of pralidoxime in humans, adverse effects are minimal.^{26,27,54–56,63,77} Transient dizziness, blurred vision, and elevations in diastolic blood pressure may be related to the rate of administration.^{33,49} Doses of 45 mg/kg produce blood pressure elevations that may persist for several hours, but may be reversed with IV phentolamine.⁷⁰ The most recent randomized clinical trial revealed a higher percentage of patients with tachycardia and hypertension associated with pralidoxime compared to placebo after both the loading dose and the continuous infusion (75% versus 49% and 30% versus 14%). Rapid IV administration has produced sudden cardiac and respiratory arrest due to laryngospasm and muscle rigidity,^{59,69,86} whereas IM administration in volunteers produced diplopia, dizziness, headache, drowsiness, nausea, tachycardia, increased systolic blood pressure, hyperventilation, decreased kidney function, muscular weakness, and pain at the injection site.⁶¹ Elevations in liver enzyme concentrations were observed in volunteers administered autoinjector doses of 1200 to 1800 mg; these enzyme concentrations returned to normal in 2 weeks.⁶¹ An important safety issue is inadvertent provider or patient contact with the “active” needle end of autoinjectors or autoinjector systems, triggering unintended administration, self-administration, needle injury, or delivery to an unintended site.

PREGNANCY AND LACTATION

Pralidoxime is FDA pregnancy risk category C. Reproduction studies have not been done, and human case reports are limited. However, considering the maternal benefit of pralidoxime, it should be used as clinically indicated to protect the maternal fetal dyad. The use of pralidoxime should not be withheld because of pregnancy.⁹ It is unknown whether pralidoxime is excreted into breast milk.

DOSING AND ADMINISTRATION

The optimal dosage regimen for pralidoxime is unknown. A maintenance dose in adults of 1 g/h of the iodide salt of pralidoxime was used in the study from India and is approximately equal to 650 mg of pralidoxime chloride.⁵⁸ The package insert, last updated in 2010, recommends a pediatric loading dose of 20 to 50 mg/kg (not to exceed 2000 mg/dose) over 15 to 30 minutes followed by a continuous infusion of 10 to 20 mg/kg/h.⁶² It recommends an adult dose of 1 to 2 g in 100 mL of 0.9% sodium chloride given intravenously over 15 to 30 minutes, with additional doses given every 3 to 8 hours as long as signs of poisoning recur.⁶² However, it does give the pharmacokinetics of a loading dose followed by a continuous infusion and comments that a loading dose followed by a continuous infusion is more likely to maintain therapeutic serum concentrations as compared to intermittent dosing.⁶² Difficulties arise because a target serum concentration in humans has not been established, although in vitro studies suggest a target concentration closer to 17 µg/mL compared with the 4 µg/mL previously suggested.^{21,23,35} This is complicated by the possibility that there is a ceiling dose and that some OP compounds are likely to be more easily reactivated than others. In addition, pharmacokinetic studies in volunteers suggest that a continuous infusion maintains a target concentration with less variation compared with intermittent boluses. Based on all of the above, we recommend a loading dose of pralidoxime chloride of 30 mg/kg (up to 2 g) over 15 to 30 minutes followed by a maintenance infusion of 8 to 10 mg/kg/h for adults (up to 650 mg/h) and 10 to 20 mg/kg/h for children (up to 650 mg/h).

The addition of 20 mL of sterile water for injection to the 1 g vial of pralidoxime results in a 5% solution (50 mg/mL). Following reconstitution, the pralidoxime should be used within several hours. This solution can be further diluted to a volume of 100 mL of 0.9% sodium chloride solution for IV infusion, or a concentration of 10 to 20 mg/mL. The loading dose can be infused over 15 to 30 minutes. If fluid overload is a concern, the 1 g of pralidoxime in 20 mL can be infused slowly over not less than 5 minutes.⁶²

Although IV administration is preferred, IM administration is acceptable using a 1 g vial of pralidoxime reconstituted with 3 mL of sterile water or 0.9% sodium chloride for injection to provide a solution containing 300 mg/mL (concentrations above 35% weight/volume produce muscle necrosis in animals).⁷¹ This could be used until an IV site is established. Patients with reduced kidney function may require dosage adjustment, but there are no specific recommendations on how to accomplish this. In patients with ARDS, the dose can be given as a 5% solution by a slow IV injection over at least 15 to 30 minutes.⁷¹

Depending on the severity of a nerve agent exposure, one to three injections with a pair of autoinjectors containing atropine and pralidoxime should be administered. The number of autoinjector doses administered to a child depends on the age and weight of the child.^{29,46} For children aged 3 to 7 (13–25 kg), one autoinjector of atropine and one autoinjector of pralidoxime should be administered, which should result in a projected pralidoxime dose of 24 to 46 mg/kg. For children aged 8 to 14, two autoinjectors of atropine and two autoinjectors of pralidoxime should be administered. These injections should result in a projected pralidoxime dose of 24 to 46 mg/kg. For anyone older than 14 years of age, three autoinjectors of atropine and pralidoxime should be administered. This results in a projected dose of pralidoxime of less than 35 mg/kg. For children younger than 3 years, during an emergency, one autoinjector of atropine and one of pralidoxime may be administered in accordance with a risk-to-benefit analysis. If time permits and only autoinjector doses are available, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.³⁰

Duration of Treatment

The signs and symptoms of OP poisoning usually manifest within minutes but may be delayed up to 24 hours.⁵⁶ Delayed manifestations occur with the fat soluble compounds, such as fenthion or chlorfenthion. The route of exposure may also influence the onset of systemic symptoms. For example, there may be a delay following dermal contact, which does not occur following ingestion or inhalation. When symptoms are either delayed or prolonged, or when treatment is delayed, extended therapy with pralidoxime may be indicated.^{1,7,53} In one case of poisoning with the fat soluble compound fenthion, 5 days elapsed before cholinergic symptoms appeared, and some symptoms then persisted for 30 days.⁵³ Pralidoxime and atropine were administered continuously in varying doses for the time that the patient was symptomatic. Therefore, the most practical recommendation is to continue the pralidoxime until symptoms have resolved and atropine has not been needed for 12 to 24 hours.¹⁸ Other recommendations for estimating the duration of pralidoxime therapy include; (1) measuring the serum or urinary concentration of the OP compound, (2) measuring serial determinations of plasma cholinesterase (increasing concentrations suggests the elimination of the OP compound), (3) incubating the patient's serum with an exogenous source of AChE or butyrylcholinesterase to assess inhibition, (4) incubating the patient's inhibited red blood cell cholinesterase with a high concentration of oxime in vitro, to assess reactivation.²¹ However, measurements of urinary concentrations of OP or AChE or plasma cholinesterase are not likely to happen in real time. Furthermore, plasma cholinesterase is not always a good surrogate for OP inhibition. In all cases, patients should be observed for the recrudescence of toxicity after termination of pralidoxime. If symptoms return, therapy should be continued for at least an additional 24 hours.

FORMULATION AND ACQUISITION

Pralidoxime chloride (Protopam) is supplied in 20 mL vials containing 1 g of powder, ready for reconstitution with sterile water or 0.9% sodium chloride for injection.^{60,62}

As noted above, pralidoxime chloride is also available for IM administration by an autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 20 mg of benzyl alcohol and 11.26 mg of glycine. The 2-PAM autoinjector is also packaged in a kit containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg of benzyl alcohol and 22.5 mg of glycine, accompanied by an autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg of glycerin and not more than 2.8 mg of phenol. This kit is called a "Mark 1 Nerve Agent Antidote Kit (NAAK)" and is designed to be used IM by first responders in case of a nerve agent attack. The needles extend 0.8 inch in length. The Mark 1 NAAK was recently replaced by the DuoDote Autoinjector System and the analogous, military designated Antidote Treatment Nerve Agent Autoinjector (ATNAA), which use technology that sequentially administers 2.1 mg of atropine in 0.7 mL followed by 600 mg of pralidoxime chloride in 2 mL IM through the same syringe.^{15a} The 23 gauge needle is 0.8 inches in length. Pralidoxime is maintained as part of the the Strategic National Stockpile (SNS) formulary in repositories in numerous locations throughout the US.

SUMMARY

- Pralidoxime is an effective reactivator of AChE in many OP compound poisonings primarily reversing neuromuscular manifestations.
- The sooner pralidoxime is administered after OP toxicity, the more effective it is likely to be, although there is no absolute time limitation on reactivation function.
- Pralidoxime and atropine are synergistic and should be used together in the management of patients with OP poisonings.
- If a patient requires multiple doses of atropine for muscarinic symptoms or has neuromuscular weakness, then the use of 2-PAM is indicated.
- The resolution of all signs or symptoms does not indicate that the enzyme systems are fully active; patients may still benefit from enzyme regeneration with the safe and effective antidote pralidoxime.
- Because newer highly fat soluble OP pesticides are currently available, it may be necessary to administer atropine and 2-PAM for more prolonged periods of time than previously suggested.

114 INSECTICIDES: ORGANIC CHLORINES, PYRETHRINS/PYRETHROIDS, AND INSECT REPELLENTS

Michael G. Holland

ORGANIC CHLORINE PESTICIDES

History and Epidemiology

Until the 1940s, commonly available pesticides included highly toxic arsenicals, mercurials, lead, sulfur, and nicotine. When Nobel Prize-winning chemist Paul Müller demonstrated the insecticidal properties of dichlorodiphenyltrichloroethane (DDT) in the early 1940s, a whole new class of pesticides was introduced. The organic chlorine insecticides were inexpensive to produce, nonvolatile, environmentally stable, and had relatively low acute toxicity when compared to previous insecticides. Most organic chlorines have a negative temperature coefficient, making them more insecticidal at lower temperatures and less toxic to warm-blooded organisms (Table 114–1).¹⁶⁴ Widespread use of these xenobiotics occurred from the 1940s until the mid 1970s. They were highly effective and revolutionized modern agriculture, allowing unprecedented crop output from each acre of arable land. Because of their stability, organic chlorines were used extensively in structural protection (termites, carpenter ants) and soil treatments. Medical and public health applications of DDT and its analogues were also found in the control of typhus and eradication of malaria by eliminating the mosquito vector.³⁴ By 1953, DDT alone was credited for saving an estimated 50 million lives and with averting one billion cases of human disease. It has also been credited with eliminating malaria from the United States and Europe. It is suggested that because of this consequential impact on human health, DDT is the single most important factor in the population explosion that occurred between 1950 and 1970.⁴⁶

TABLE 114–1. Classification of Organic Chlorine Pesticides

<i>Classes of Organic Chlorines</i>	<i>Specific Organic Chlorine; CAS Registry#</i>	<i>Brand Name(s)</i>	<i>Current EPA Registration (US)</i>	<i>Acute Oral Toxicity (Man)</i>	<i>Dermal Absorption</i>	<i>Lipid Storage</i>	<i>Specific Characteristics</i>
Hexachloro-cyclohexanes	Lindane (γ isomer) 58–89–9	Kwell; Gustafson Flowable; Sorghum Guard	Topical scabicide; Agricultural use cancelled 2006	Moderate	High	Low	Topical scabicide; Seizures; CNS excitation; musty odor
DDT and analogues	DDT-Dichlorodiphenyltrichloroethane 50–29–3	Neocid, Ioxodex, Anofex, others	Cancelled 1972	Low to moderate	Low	Highest	Tremors, CNS excitation; odorless
	Methoxychlor 72–43–5	Marlate	Cancelled 2003	Low	Low	Moderate	Less toxic DDT substitute
	Dicofol 115–32–2	Kelthane	Residential Use Banned 1998; Cotton, Citrus, Apple	Low	Low	Low	
	Chlorobenzilate 510–15–6	Benzilan, BenzoChlor	Cancelled 1983	Low	Low	Low	Much less environmental persistence than DDT
Cyclodienes and related compounds	Aldrin 309–00–2	Aldrex, Octalene, Toxadrin	Cancelled 1974	High	High	High	Rapidly metabolized to Dieldrin; mild “chemical” odor
	Dieldrin 60–57–1	Dieldrine, Octalox, Quintox	Cancelled 1974	High	High	High	Stereoisomer of Endrin; early and late seizures; odorless
	Endrin 72–20–8	Hexadrin	Cancelled 1974	Highest	High	None	Most toxic organic chlorine; rapid onset seizures, status epilepticus
	Chlordane 57–74–9	Octachlor, Toxichlor, others	Cancelled 1988	Moderate	High	High	Early and late seizures occur
	Endosulfan 115–29–7	Thiodan, Cyclodan, others	RED ^a 2002	High	High	Low	Strong sulfur odor
	Heptachlor 76–44–8	Drinox	Restricted: fire ant control, soil treatment	Moderate	High	High	Toxic metabolite heptachlor epoxide; odor of camphor
	Isobenzan 297–78–9	Telodrin	Never Registered	High	Moderate	High	Also inhibits Mg ⁺⁺⁺ -ATPase; mild “chemical” odor
	Thenachlor 2227–17–0 Toxaphene (Polychlorinated Camphene) 800–35–2	Pentac Alltox, Chemphene, Toxakil, others	Cancelled Cancelled 1982	NA Moderate to high	Low Low	Low Low	Toxic metabolite binds to GSH Seizures; turpentine-like odor, often mixed with parathion
Chlordecone and Mirex	Chlordecone 143–50–0	Kepone	Cancelled 1977	Moderate	High	High	“Kepone shakes”; seizures not seen, structurally similar to mirex
	Mirex 2385–85–5	Dechlorane	Cancelled 1976	Low	High	High	(?) Converted to chlordecone, toxicity identical

^aChemical Abstracts Service # provided here to facilitate Toxline, Medline database searches. ^bRED = Re-registration eligibility decision.

However, the properties that made these chemicals such effective insecticides also made them environmental hazards; they are slowly metabolized, lipid soluble, chemically stable, and environmentally persistent. In her 1962 book, *Silent Spring*, Rachel Carson, a biologist with the US Fish and Wildlife Service, demonstrated that organic chlorines are bioconcentrated and biomagnified up the food chain.¹⁹ She alleged that this persistence could eventually lead to increases in cancer in the future. Extensive environmental research demonstrates that organic chlorine residues caused eggshell thinning and decreased reproductive success in predatory birds, most notably grebes, peregrine falcons, bald eagles, and pelicans.⁴⁵ However, conflicting results were seen when DDT-laced feedstuffs were administered in high concentrations to experimental birds. Testing on domesticated birds, such as Japanese quail^{21,26,121} and chickens,¹⁶² showed little or no eggshell thinning, whereas testing on mallard ducks showed thinning.^{40,41} Hearings before the Environmental Protection Agency (EPA) regarding DDT registration focused also on the unproven fear of placing future generations at risk of cancer. This fear, and the demonstration of persistent DDT residues in all humans, even those living in areas where DDT was never utilized (eg, Eskimos), led to the severe restriction or total ban of DDT and most other organic chlorines in North America and Europe.³⁴ There is considerable evidence that since DDT was banned, less-effective replacements have placed many more millions of people at risk for malaria and are responsible, at least in part, for millions of deaths from this disease.^{95,118,119} Not surprisingly, DDT is still considered a highly effective mosquito control agent with a low order of acute toxicity, and it is very inexpensive compared to newer replacement insecticides. For these reasons, the World Health Organization (WHO) exempted DDT from its list of banned pesticides, and it is still widely used for malaria control

programs in many countries since alternatives are more expensive and must be applied more often. Current use of DDT for indoor residual spraying is ongoing in endemic areas in Africa and has been shown to be safe and effective as a public health initiative to control malaria, even in areas with resistant strains.¹²⁷ In 2006, the EPA officially cancelled the registration for lindane and all use in agriculture ceased in 2009.¹⁵⁷

Organic chlorine pesticides are complex, cyclic polychlorinated hydrocarbons having molecular weights generally in the range of 300 to 550 Da. They are nonvolatile solids at room temperature. Most act as central nervous system stimulants. In contrast, chlorinated hydrocarbon solvents and fumigants are low molecular weight, alkyl compounds that are volatile liquids or gases and generally have CNS depressant effects (Chap. 108).

The organic chlorine pesticides can be grouped into four categories based on their chemical structures and similar toxicities: (a) DDT and related analogues; (b) cyclodienes (the related isomers aldrin, dieldrin, and endrin; and heptachlor, endosulfan), and related compounds (toxaphene, dienochlor); (c) hexachlorocyclohexane, the primary organochlorine pesticide still in clinical use as a pediculocide (more commonly termed lindane, the γ isomer; also referred to by the misnomer γ -benzene hexachloride). Specifying the exact isomer is important with this compound, because the β and δ isomers are CNS depressants and have no insecticidal properties,^{3,32,108} and (d) mirex and chlordane (Table 114–1; Fig. 114–1). These organic chlorine insecticide compounds differ substantially, both between and within groups, with respect to toxic doses, skin absorption, fat storage, metabolism, and elimination.³⁴ The signs and symptoms of toxicity in humans, however, are remarkably similar within each group.

FIGURE 114–1. Structures of various organic chlorine pesticides.

Toxicokinetics

Absorption. All the organic chlorine pesticides are well absorbed orally and by inhalation; transdermal absorption is variable, depending on the particular xenobiotic. Absorption by any route may be affected by the vehicle and the physical state (solid or liquid) of the pesticide. Organic chlorines are not water-soluble, and they are usually either dissolved in organic solvents or manufactured as powders for dusting.

DDT and its analogues, methoxychlor, dicofol, and chlorobenzilate, are very poorly absorbed transdermally, unless the pesticide is dissolved in a suitable hydrocarbon solvent.¹¹⁶ DDT has limited volatility, so air concentrations are usually low, and toxicity by the respiratory route is unlikely.

All the cyclodienes have significant transdermal absorption rates. Cutaneous absorption of dieldrin is approximately 50% of the oral route. Oral absorption of the cyclodienes is also high, and significant poisonings have occurred when foodstuffs were contaminated with these pesticides.^{17,23} Toxaphene is poorly absorbed through the skin in both acute and chronic exposures.¹³²

Lindane is well absorbed after skin application, and in adults it has a documented forearm skin absorption rate of 9.3% of a topically applied dose over 24 hours.⁵⁴ Anatomic sites vary in their absorptive capacities: axillary rates are 3.6 times greater, and scrotal absorption is 42 times greater than that of forearm rates.^{14,58,73,142} Animal studies and case reports suggest that the young, the malnourished, and those who receive repeated topical doses may have increased accumulation and increased toxicity.¹⁰⁹ Hot baths, occlusive clothing or bandages, the vehicle for the lindane, and a disturbed cutaneous

integrity, such as eczema, fissures, and other violations of the skin, all enhance dermal penetration.^{141,142} The state of hydration of the skin also affects the amounts absorbed, so bathing just prior to application can enhance absorption and increase the likelihood of toxicity.^{93,142} Lindane is a stable compound and volatilizes easily when heated. It was previously used extensively in home vaporizers, and toxicity was common via inhalation and when vaporizer tablets were unintentionally ingested by children. Review of data when lindane was ingested therapeutically as an anthelmintic demonstrates that 40 mg/d for 3 to 14 days generally produced no symptoms.³⁴ Mirex and chlordecone are efficiently absorbed via skin, by inhalation, and orally.⁵³

Distribution. All organic chlorines are lipophilic, a property that allows penetration to their sites of action.²⁸ The fat-to-serum ratios at equilibrium are high, in the range of 660:1 for chlordane,⁶² 220:1 for lindane,¹³³ and 150:1 for dieldrin.³⁵ Central nervous system redistribution of the organic chlorines to the blood and then to fat may account for the apparent rapid CNS recovery despite the persistent substantial total body burden. In the rat model, there is a direct correlation between the concentration of DDT or dieldrin in the brain and the clinical signs produced after a single dose of the insecticide.^{34,38}

Metabolism. The high lipid solubility and very slow metabolic disposition of DDT, DDE (dichlorodiphenyl dichloroethylene, a metabolite of DDT), dieldrin, heptachlor, chlordane, mirex, and chlordecone causes significant adipose tissue storage and increased body burdens in chronically exposed populations.⁵³ Organic chlorines that are rapidly metabolized and eliminated, such as endrin (an isomer of dieldrin), endosulfan, lindane, methoxychlor, dienochlor, chlorobenzilate, dicofol, and toxaphene tend to have less persistence in body tissues, despite being highly lipid soluble.¹¹⁶

Most organic chlorines are metabolized by the hepatic microsomal enzyme systems by dechlorination, oxidation, with subsequent conjugation. However, metabolism may result in the production of a metabolite with more toxicity than the parent compound, such as heptachlor to heptachlor epoxide, chlordane to oxychlordane, and aldrin to dieldrin.

In animals, most organic chlorine pesticides are capable of inducing the hepatic microsomal enzyme systems.^{33,166} Enzyme induction changes the biodegradation of the pesticide in rodents,¹⁴⁸ and in certain animal models the acute toxicity of organic phosphorus compounds and carbamates may be reduced by the administration of organic chlorines. This protective effect is presumably induced by the hepatic microsomal metabolism of the organic phosphorus compound because this effect is ameliorated by administering piperonyl butoxide, an inhibitor of the liver microsomal enzyme system.^{34,166} However, induction of hepatic enzymes has not been described in humans, except in rare cases of massive exposure with concomitant neurologic findings.^{53,62}

Elimination. The half-lives of fat-stored compounds and poorly metabolized organic chlorines, such as DDT and chlordecone, are measured in months or years, compared to the elimination half-life of lindane, which is 21 hours in adults.⁹⁴ The primary route of excretion of organic chlorines is in the bile, but most also have detectable urinary metabolites. However, as with other compounds excreted in bile, most organic chlorines, such as mirex and chlordecone, have significant enterohepatic or enteroenteric recirculation.^{12,31,53} All the lipophilic compounds are excreted in maternal milk.¹²²

Mechanisms of Toxicity

The same neurotoxic properties that make organic chlorines lethal to target insects make them potentially toxic to higher forms of life. Organic chlorines exert their most important effects on the central nervous system. Electrophysiologic studies demonstrate that organic chlorine insecticides affect the neuronal membrane by either interfering with repolarization, by prolonging depolarization, or by impairing the maintenance of the polarized state of the neuron. The end result is hyperexcitability of the nervous system and repetitive neuronal discharges.⁴⁶

The voltage-gated Na⁺ channel is a common site of action for neurotoxins, both natural and synthetic. There are at least 10 separate binding sites on the Na⁺ channel, including those for local anesthetics and anticonvulsants. DDT, as well as the pyrethroids (see below), bind at the same site on these channels. They preferentially bind when the channel is in the open state, allowing prolonged inward sodium conductance, repetitive action potentials, and extended tail currents. Prolonged axonal firing and repetitive stimulus eventually leads to nerve paralysis and death in target insects, whose Na⁺ channels have much greater affinity for these insecticides than those in mammals.^{98,99,143,102} In mammals, low-level stimuli cause exaggerated responses, manifested clinically as prominent tremors and abnormal startle reflexes observed in test animals.^{70,155} Evidence of this as the primary mechanism of action is the amelioration of DDT-induced tremor by pretreatment with phenytoin, a Na⁺ channel blocker, which reduces the ability of voltage-dependent Na⁺ channels to recover from inactivation.^{70,156}

The cyclodienes and lindane act as γ -aminobutyric acid (GABA) antagonists. They inhibit GABA binding at the GABA_A receptor-chloride ionophore complex in the CNS, by interacting at the picrotoxinin binding site.^{3,9,32,61,66,101,108} In fact, the degree of binding at this site correlates well with the amount of Cl⁻ influx inhibited and the relative neurotoxicity

of each insecticide^{9,61} (Figs. 14–9, 14–10, and 114–2). Indeed, development of cyclodiene resistance seems to be related to alterations of the GABA_A-receptor-chloride ionophore complex in these affected insects.^{10,99} This also explains the efficacy of GABA agonists, such as benzodiazepines and phenobarbital, in treating the seizures and neurotoxicity of the cyclodienes⁶⁷ and lindane.¹⁷⁰ Toxaphene also inhibits GABA binding at the GABA_A receptor-chloride ionophore complex.¹³²

FIGURE 114–2. Chloride channel. Under resting conditions, a tonic influx of chloride maintains the nerve cell in a polarized state. Binding of GABA or an indirect-acting GABA agonist (benzodiazepine, barbiturate, volatile anesthetic) opens the chloride channel. The subsequent chloride influx hyperpolarizes the cell membrane, making the neuron less likely to propagate an action potential in response to a stimulus. GABA antagonists, such as picrotoxin, close the chloride channel, reducing chloride influx. The resulting decreased membrane polarity causes the neuron to become hyperexcitable to even those stimuli that are normally subthreshold in nature (Chap. 14).

The mechanisms of action of mirex and chlordecone are not as well understood. They inhibit Na⁺-K⁺-ATPase and Ca²⁺-ATPase. However, lindane, DDT, and the cyclodienes also inhibit these enzymes yet produce very different symptoms of toxicity, suggesting that these effects are not responsible for the clinical manifestations seen in mirex and chlordecone toxicity. Phenytoin and serotonin agonists exacerbate the prominent tremor that occurs with chlordecone intoxication, but conversely attenuate the tremors in DDT poisoning, which further supports a different mechanism than the Na⁺ channel effects of DDT.⁴⁶ Mirex and chlordecone are poor inhibitors of GABA binding at the GABA_A-receptor-chloride ionophore complex; therefore, their mechanism of action is likely not at this site,⁵³ and seizures are not described

with mirex or chlordane. Organic chlorines can predispose test animals to cardiac dysrhythmias,¹¹⁶ presumably via myocardial sensitization, similar to chlorinated hydrocarbon solvents (Chap. 108).

Drug Interactions

There are theoretical consequences of liver enzyme induction, such as enhanced metabolism of therapeutic drugs and reduced efficacy. Dysfunctional uterine bleeding was attributed to enhanced oral contraceptive metabolism induced by chlordane, but this report involved a single patient with weeks of excessive exposure to chlordane.⁶² A large group of workers poisoned by chlordane over many months had some increased hepatic microsomal activity, but there was no evidence of drug interactions or adverse clinical effects.⁵³ Thus, induction of the hepatic microsomal enzyme system by organic chlorines probably occurs only with extended, substantial exposure.¹¹⁶ There are no definitive reports of enhanced metabolism of therapeutic drugs or adverse reactions because of microsomal enzyme induction in humans.

Clinical Manifestations

Acute Exposure. In sufficient doses, organic chlorines lower the seizure threshold (DDT and related Na⁺ channel agents) or remove inhibitory influences (antagonism to GABA effects) and produce CNS stimulation, with resultant seizures, respiratory failure, and death^{20,23,29,66,67,80,81,125,126} After DDT exposure, tremor may be the only initial manifestation. Nausea, vomiting, hyperesthesia of the mouth and face, paresthesias of face, tongue, and extremities, headache, dizziness, myoclonus, leg weakness, agitation, and confusion may subsequently occur. Seizures only occur after very high exposures, usually following large ingestions^{46,67} DDT has a relatively low order of acute toxicity, and high doses of DDT (>10 mg/kg or more) are usually necessary to produce symptoms⁶⁷ However, with lindane, the cyclodienes, and toxaphene, there often are no prodromal signs or symptoms, and more often than not, the first manifestation of toxicity is a generalized seizure^{20,23,46,45,67,81,125,145} If seizures develop, they often occur within 1 to 2 hours of ingestion when the stomach is empty, but they may be delayed as much as 5 to 6 hours when the ingestion follows a substantial meal⁶⁷

Seizures related to dermal application of 1% lindane for treatment of ectoparasitic diseases may occur following a single inappropriate application,^{86,109,153} or, more commonly, after repetitive and prolonged exposures.^{83,113} The time from application to seizure onset can vary from hours to days. The seizures are often self-limited, but may recur or result in status epilepticus. Analysis of an epidemic of lindane poisoning related to the unintentional substitution of lindane powder for sugar used in coffee demonstrated a delay of 20 minutes to 3 hours before the onset of nausea, vomiting, dizziness, facial pallor, severe cyanosis of the face and extremities, collapse, convulsions, and hyperthermia. Affected patients ingested an average of 86 mg/kg of lindane in a single dose.³⁴

The cyclodienes are also notable for their propensity to cause seizures that may recur for several days following an acute exposure. If the seizures are brief and hypoxia has not occurred, recovery is usually complete. Electroencephalographic (EEG) abnormalities have been recorded before, during, and following seizures.⁸¹ Hyperthermia secondary to central mechanisms, increased muscle activity, or aspiration pneumonia is common.⁴⁶

Status epilepticus is a common occurrence in patients with intentional endosulfan ingestions. A recent abstract summarized 25 cases of endosulfan self-poisonings with resultant status epilepticus in Nepal. More than half of the patients developed refractory status epilepticus, and eight patients died.⁸⁸

The ingestion of combinations of xenobiotics may result in significantly increased toxicity—probably the result of synergy. This has been demonstrated for DDT and lindane.⁶⁷

Lindane: Specific Risks. Patients are at risk for developing central nervous system toxicity from improper topical therapeutic use, such as exceeding recommended application times or amounts, repeated applications, application following hot baths, and use of occlusive dressings or clothing shortly after application. Toxicity also occurs after unintentional oral ingestion of topical preparations. Young children appear at greatest risk, possibly because of greater skin permeability, increased ratio of body surface area to mass, or immature liver enzymes^{113,152,153} The elderly may also be at increased risk because of impaired hepatic metabolism, atrophic skin, and perhaps age-related increased sensitivity. Patients at increased risk also include those with preexisting conditions that cause increased risk of seizures, such as treatment with antipsychotics, which lower the seizure threshold, CNS disease, or skin absorption changes^{4,36,55,83,86,103,109,113,141,142,152,153}

Despite the availability of safer and equally or more effective treatments such as permethrin, lindane had continued to be used because of its lower cost than permethrin and generally good safety profile, when used according to directions. However, now that permethrin products are available in less-expensive generic forms, the cost advantage of lindane is gone, and it is being used less each year.

An evaluation of published English-language case reports and those submitted to the US Food and Drug Administration (FDA) divided toxicity into those associated with concentrations of lindane greater than or less than 1%.⁸³ Only 6 of 26 cases could be considered related to 1% lindane;⁴ six of these cases were the result of ingestion or inappropriate skin

application.⁴ However, a recent comprehensive review of all published adverse events associated with topical lindane (67 cases) showed that while most of the serious adverse reactions (16 deaths, 11 seizures) occurred in ingestions or excessive use, labelled use accounted for a substantial portion of serious adverse reactions (4 deaths, 11 seizures).¹⁰⁰ The sale of lindane-containing products for use in humans was banned in California in 2004 because of its toxicity and environmental concerns.¹⁷ In 1995, the FDA changed the labeling requirements for lindane, adding a black-box warning and relegating it to second line therapy for ectoparasitic skin infections, due to its toxicity and to the superior safety and efficacy of other products.¹⁵⁸

Chronic Exposure. Chlordecone (Kepone), unlike the other organic chlorines, produces an insidious picture of chronic toxicity related to its extremely long persistence in the body. Because of poor industrial hygiene practices in a makeshift chlordecone factory in Hopewell, Virginia, 133 workers were heavily exposed for 17 months between 1974 and 1975. They developed a clinical syndrome which became known as the “Hopewell epidemic,” which consisted of a prominent tremor of the hands, a fine tremor of the head, and trembling of the entire body, known as the “Kepone Shakes.” Other findings included weakness, opsoclonus (rapid, irregular, dysrhythmic ocular movements), ataxia, altered mental status, rash, weight loss, and elevated liver enzymes. Idiopathic intracranial hypertension, oligospermia, and decreased sperm motility were also found in some of these workers. Severely affected workers even exhibited an exaggerated startle response, remarkably similar to that seen in animal studies. The exposures were so intense that some workers went home covered with chlordecone, and several workers’ wives developed neurologic symptoms, presumably from exposures while laundering their husbands’ work clothes.^{53,31}

There is much concern in environmental health centers on persistent organic chemicals, organic chlorine residues and PCBs being prime examples. A recent review of the world literature reveals that since being outlawed in many processes and countries, human burden appears to be decreasing.⁹⁰

DDT and Breast Cancer. DDT and other organic chlorine insecticides have estrogenic effects.^{37,144} Since breast cancer incidence rates in the United States have steadily climbed 1% per year since the 1940s, coinciding with the worldwide use of DDT, it has been postulated that women who have higher concentrations of estrogenic organic chlorines compounds (eg, DDT, polychlorinated biphenyls {PCBs}) may be at risk for developing breast cancer.^{128,129,130,130,168}

Several small case-control studies of women with breast cancer showed that women with the disease had higher average body burdens of DDT, DDE, and PCBs than their age-matched controls. These studies implicated organic chlorines as a possible cause of human breast cancer. Recently, however, larger studies have shown no increased risk of breast cancer because of exposure to organic chlorines¹⁸ and that currently accepted hereditary and lifestyle risk factors were present in the patients with cancer.^{71,84,130,129,128} In fact, other natural dietary estrogens, such as flavonoids, lignans, sterols, and fungal metabolites, are present in the human diet and have much higher estrogenic potency; the organic chlorine contribution is probably minimal by comparison.⁶⁰ One interesting report suggests age at first exposure, that is, age <14 years (prior to menarche) as having an association with later breast cancer,³⁰ but most case-control studies recently published have not supported an association between DDT and breast cancer.^{15,63,72,74,138,139} A meta-analysis of 22 studies found strong evidence to discard the putative relationship between p, p'-DDE levels and breast cancer risk.⁸⁹

Diagnostic Information

The history of exposure to an organic chlorine pesticide is the most critical piece of information because exposure is otherwise rare. By law, the package label of these products must list the ingredients, the concentrations, and the vehicle. The EPA-registered use of the insecticide may be helpful in determining which agent is involved. The presence of an unusual odor in the mouth, in the vomitus, or on the skin may be helpful. Toxaphene, a chlorinated pinene, has a mild turpentinelike odor, and endosulfan has a unique “rotten egg” sulfur odor (Table 114–1). Following ingestion, an abdominal radiograph may reveal the presence of a radiopaque chlorinated pesticide, since chlorine increases the radiopacity of the xenobiotics (Chap. 5). A large number of other xenobiotics lead to seizures as the first manifestation of toxicity and must be considered in the differential of an unknown exposure (Chaps. 14 and 24).

Laboratory Testing

Gas chromatography can detect organic chlorine pesticides in serum, adipose tissue, and urine.^{35,71} If confirmation is necessary for purposes of documentation of source, it may be necessary to measure concentrations of organic chlorines. If the patient’s history and toxidrome are obvious, then laboratory evaluation is unnecessary, as this determination will not alter the course of management, and these blood tests are not available on an emergent basis. At present, there are no data correlating health effects and tissue concentrations. Routine surveillance of serum concentrations in the occupationally exposed is not currently performed.³⁵

Most humans studied have measurable concentrations of DDT in adipose tissue. In a study of a community with a very large exposure to DDT, serum DDT concentrations increased proportionally with age. These increasing concentrations were not associated with any apparent adverse health effects, but there was an association with increasing concentrations

of the liver enzyme γ -glutamyltransferase (GGT), although significant hepatotoxicity did not occur. The CDC's Third National Report on Human Exposure to Environmental Chemicals demonstrated the presence of numerous organic chlorine pesticide residues in lipid fraction of serum of US residents. These concentrations tend to increase with patient age, consistent with the bioaccumulation and fat-storing properties of the chemicals.²⁴ More recently, studies of occupationally-exposed pesticide applicators and persons living in targeted regions confirmed higher serum concentrations over those not exposed, but no ill health effects are documented.¹²⁷

Serum lindane concentrations can be used to document exposure, and clinical signs and symptoms of toxicity correlated with blood concentrations.³¹ Lindane-exposed workers with chronic neurologic symptoms showed blood lindane concentrations of 0.02 mg/L.^{4,67} A limited series of patients with acute lindane ingestion suggests that a serum concentration of 0.12 mg/L correlates with sedation, and that 0.20 mg/L is associated with seizures and coma.⁴ After cutaneous application, lindane concentrations in the CNS are 3 to 12 times higher than serum concentrations.^{39,142}

Management

As with any patient who presents with an altered mental status, the administration of dextrose and thiamine in an adult should be considered. Skin decontamination is essential. Clothing should be removed, placed in a plastic bag, and disposed of appropriately as a biohazardous waste; the skin must be washed with soap and water. Health care providers should be protected with rubber gloves and aprons. Because these pesticides are almost invariably liquids, a nasogastric tube can be used to suction and lavage gastric contents, if clinically indicated. This is most appropriate only with very recent ingestion (Chap. 8). Activated charcoal (AC) can be used after or instead of gastric lavage, when lavage is not indicated.^{67,92} However, the ability of AC to adsorb the various organic chlorines is not adequately studied, and mixtures containing petroleum distillates would obviously preclude the use of AC (Chap. 20). Because organic chlorines are all neurotoxins, the risk of complications associated with seizures probably outweighs the risk of any of the GI decontamination strategies in most acute settings. A murine model of lindane toxicity following intragastric administration showed a trend, but not a statistically significant benefit, of AC. The use of cholestyramine, a nonabsorbable bile acid-binding anion exchange resin, in the same murine model did show a statistically significant benefit by raising both the convulsive dose and the lethal dose.⁷⁸ Oil-based cathartics should never be used, as they may facilitate absorption. There is some evidence that sucrose polyester (olestra, a nonabsorbed synthetic dietary oil substitute) can increase excretion of a wide variety of fat-soluble organic chlorine chemicals.^{75,96} This effect was demonstrated in dioxin-poisoned patients when administered in potato chips,⁶⁴ and was recently employed in treating Ukrainian President Viktor Yushenko.¹⁴⁶ Sucrose polyester might be an inexpensive and more palatable alternative to cholestyramine to increase excretion in patients with increased body burdens from chronic organic chlorine toxicity.

Seizures should be controlled with a benzodiazepine followed by pentobarbital or a propofol infusion and, if necessary, neuromuscular blockade to control the peripheral manifestations of seizures, thereby preventing metabolic acidosis and rhabdomyolysis. As has been shown in other toxic exposures, phenytoin is much less effective in these cases, particularly with the GABA-chloride ionophore antagonists lindane, toxaphene, and the cyclodienes.¹¹⁶ Hyperthermia should be managed aggressively with external cooling.

Cholestyramine should be administered to all patients symptomatic from chlordecone, and possibly other organic chlorines. Chlordecone undergoes both enterohepatic and enteroenteric recirculation, which can be interrupted by cholestyramine at a dosage of 16 g/d. Cholestyramine increased the fecal elimination of chlordecone 3-to 18-fold in industrial workers exposed during the Hopewell epidemic, resulting in clinical improvement.³¹ Sucrose polyester may also be an option for enhancing excretion.

PYRETHRINS AND PYRETHROIDS

The pyrethrins are the active extracts from the flower *Chrysanthemum cinerariaefolium*. These insecticides are important historically, having been used in China since the 1st century A.D.³⁴ and developed for commercial application by the 1800s. They are produced by organic solvent extraction from ground *Chrysanthemum* flowers. The resulting concentrates have greater than 90% purity. Pyrethrum, the first pyrethrin identified, consists of six esters derived from chrysanthemic acid and pyrethric acid. These insecticides are highly effective contact poisons, and their lipophilic nature allows them to readily penetrate insect chitin (exoskeleton) and paralyze the nervous system through Na^+ channel blockade.^{28,97,143,116} When applied properly, they have essentially no systemic mammalian toxicity because of their rapid hydrolysis. Pyrethrins break down rapidly in light and in water, and therefore have no environmental persistence or bioaccumulation. This fact makes them extremely safe after human exposures, but unsuitable for commercial agriculture, since the constant reapplication would be cost prohibitive.

The pyrethroids are the synthetic derivatives of the natural pyrethrins¹⁴⁰ (Table 114–2 and Fig. 114–3). They were developed in an effort to produce more environmentally stable products for use in agriculture. Originally, the pyrethroids

were divided into two groups based on the toxic syndromes they elicited in test animals. The T syndrome (for tremor seen in rats) was produced by intravenous administration of pyrethrin and most (15 of 18) of the pyrethroids that did not contain a cyano group at the central ester linkage (see below). The CS syndrome (for choreoathetosis and salivation) was produced by 12 of the 17 pyrethroids that had an α -cyano group at the ester linkage. The original studies delineating the T or CS method of classification did not test several new currently registered pyrethroid pesticides, and the testing methods involved intravenous or intracerebral administration, which are not relevant to human exposures.¹⁴⁰

TABLE 114-2. Synthetic Pyrethroids in Common Use

Pyrethroid Class	Generic Name, CAS #	Trademark Brand Names	Generation of Pyrethroid, Dates Introduced (if Available)
Type I	Allethrin 584-79-2	Pynamin	1st generation; first synthetic pyrethroid, 1949
	Bioallethrin 584-79-2	D-Trans	2nd generation, 1969; trans isomer of allethrin
	Dimethrin 70-38-2	Dimetrix	
	Phenothrin 26002-80-2	Fenothrin, Forte, Sumithrin	2nd generation, 1973
	Resmethrin 10453-86-8	Benzofluorene, Chrysion, Crossfire, pyrethrum Premgard, Pynosect, Pyrethrin, Synthrin	2nd generation, 1967; 20X strength of pyrethrum
	Bioresmethrin 28434-01-7		2nd generation, 1967; 50X strength of pyrethrum, isomer of resmethrin
	Tetramethrin 7696-12-0	Neo-Pynamin	2nd generation, 1965
	Permethrin 52645-53-1	Ambush, Biomist, Dragnet, Ectiban, Elmite, Iptox, Ketokill, Nix, Outflank, Perigen, Permasect, Persect, Pertox, Pounce, Prames, etc	3rd generation, 1972; effective topical scabicide and miticide, low toxicity
	Bifenthrin 82657-04-3	Capture, Talstar	4th generation
	Prallethrin 23031-36-9	SF, Etox	4th generation
	Imiprothrin 72963-72-5	Multicide, Pralle, Raid Ant & Roach	3rd generation, 1998
Type II	Fenvalerate 51630-58-1	Belmark, Evercide, Extrin, Fenkill, Sanmarton, Sumicidin, Sumilly, Sumipower, Sumitox, Tribute	3rd generation, 1973
	Azinathrin 103833-18-7	Rufast	4th generation
	Cyfluthrin 68359-37-5	Baythroid, Countdown, Cylense, Laser, Tempo, Bulldock, Cyfloxylate, Eulan SP, Solfac	4th generation
	Cyhalothrin 91465-08-6	Demand, Karate, Ninja 10WP, Scimitar, Warrior	4th generation
	Cypermethrin 52315-07-8	Ammo, Barricade, CCNS2, Cymbush, Cyperator, Cynoff, Cypercopal, Cyperkill, Cynuc, Demon, Electron, Kahl/Super, Ripcord, Siperin, Mustang & Fury	4th generation
	Deltamethrin 52918-63-5	Butolin, Butox, Crackdown, Decis, DeltaDust, DeltaGard, Deltex, K-Othrine, Striker, Suspend	4th generation
	Esfenvalerate 66230-04-4	Asana, Asana-XL, Hallmark, Sumi-alpha	4th generation
	Fenpropathrin 39515-41-8	Danitol, Herald, Meothrin, Rody	4th generation, 1989
	Flucythrinate 70124-77-5	AASTAR, Cybolt, Floent, Payoff, Guardian, Cythrin, StockGuard	4th generation
	Fluvalinate 102851-06-9	Apistan, Klaran, Mavrik, Mavrik Aqua Flow, Spur, Taufluvalinate, and Yandex	4th generation
	Imiprothrin 72963-72-5	Pralle; Multicide (mixture with d-phenothrin)	4th generation, 1998
	Tefluthrin 79538-32-2	Demand, Force, Karate, Scimitar, Evict, Fireban, Force & Raze	4th generation
	Tralomethrin 66841-25-6	Dethmor, SAGA, Scout, Scout X-TRA, Tralex	4th generation

FIGURE 114–3 Representative structures of pyrethrin and pyrethroids.

The predominant classification scheme used today is based on the structure of the pyrethroid, its clinical manifestations in mammalian poisoning, its actions on insect nerve preparations, and its insecticidal activity. Type I pyrethroids have a simple ester bond at the central linkage without a cyano group. Commonly used type I pyrethroids include permethrin, allethrin, tetramethrin, and fenothrin. The type II pyrethroids have a cyano group at the carbon of this ester linkage. Type II pyrethroids in common use include cypermethrin, deltamethrin, fenpropathrin, fluvalinate, and fenvalerate. The cyano group greatly enhances neurotoxicity of the type II pyrethroids in both mammals and insects, and type II pyrethroids tend to produce the CS syndrome in test animals and are generally considered more potent and toxic than the type I pyrethroids (Fig. 114–3).^{45,91,115,116,140}

The development of the pyrethroids can also be divided into “generations,” based on efficacy and dates of introduction.¹⁶⁴ The first generation began in 1949, with the development of allethrin. The second generation began in 1965, with the introduction of tetramethrin. The major advance of the second generation was a dramatic increase in potency compared with the pyrethrins. The third generation, introduced in the 1970s and including fenvalerate and permethrin, were the first pyrethroids with practical agricultural use. They were more potent, and more environmentally stable, with efficacious crop residues lasting 4 to 7 days. The current fourth generation includes mostly type II pyrethroids, which have even greater insecticidal activity, are photostable (do not undergo photolysis, “splitting,” in sunlight), have minimal volatility, and provide extended residual effectiveness for up to 10 days under optimum conditions.^{91,164}

There are more than 1000 pyrethroids, of which 16 to 20 are in widespread use today.^{34,13} Pyrethrins and pyrethroids

are found in more than 2000 commercially available products. These insecticides have a rapid paralytic effect (“knock down”) on insects. Most mammalian species are relatively resistant because the pyrethrins can be rapidly detoxified by ester cleavage and oxidation.¹⁰⁷ Toxicity of the pyrethrins and pyrethroids is enhanced in insects by combination with microsomal enzyme inhibitors such as piperonyl butoxide (a synthetic analogue of sesamin, the methylenedioxyphenyl component of sesame oil) or N-octyl bicycloheptene dicarboximide.^{8,111}

Permethrin, a type I pyrethroid, is used medicinally for topical treatment of ectoparasitic conditions in humans, and it is impregnated in clothing and mosquito netting for its insect repellent properties. It has an excellent safety profile, with approximately 2% or less absorbed systemically through the skin.⁹³ Recent comprehensive reviews have confirmed that 5% permethrin is the drug of choice for scabies treatment, with the best efficacy versus safety profile of topical treatments for scabies and lice.^{123,163}

West Nile Virus was first identified in the United States in 1999 and rapidly spread to most of the United States by 2006. Outbreaks of encephalitis caused by West Nile virus (WNV) have occurred in the late summer and early autumn months in the United States since 1999. Although birds are the reservoirs for WNV, transmission to humans occurs via mosquito bites, and hence many states and municipalities have increased their aerial spraying in an effort to control mosquitoes vectors of this disease. Most spraying programs use pyrethroid insecticides because of their favorable safety profile and their efficacy against the adult mosquito. These widespread spraying programs have increased the potential for human exposures to these xenobiotics. A Centers for Disease Control and Prevention study of pyrethroid spraying did not reveal an increase in detectable pyrethroid metabolites in the general public living in the sprayed areas.⁷ Another study of asthma surveillance showed no increases in emergency department visits because of asthma-related conditions for the periods after pyrethroid spraying.⁷⁶

Toxicokinetics

Absorption. Pyrethrins are well absorbed orally and via inhalation, but skin absorption is poor. Piperonyl butoxide is also well absorbed orally, but likewise has poor dermal penetration.¹¹¹ The oral toxicity of pyrethrins in mammals is extremely low because they are so readily hydrolyzed into inactive compounds. Their dermal toxicity is even lower, owing to their slow penetration and rapid metabolism.^{46,107}

The pyrethroids are more stable than the natural pyrethrins, and significant systemic toxicity occurs following ingestion.⁶⁸ An average of 35% (range 27%–57%) of orally administered cypermethrin is absorbed in human volunteers.¹⁶⁹ Most exposures are from dermal absorption, the rate of which may vary depending on the solvent vehicle. In the same volunteer study noted above, a mean of 1.2% (range 0.85%–1.8%) of dermally applied cypermethrin in soybean oil vehicle was absorbed systemically.¹⁶⁹ Intradermal metabolism of pyrethroids is documented in test animals and likely further limits systemic absorption.¹³ Direct absorption of pyrethroids through the skin to the peripheral sensory nerves probably accounts for the facial paresthesias that occur in these cases, as symptoms were prominent in areas of direct contact.^{27,85} Absorption probably also occurs through the oral mucosa, as noted by a large study of Chinese insecticide sprayers who frequently used their mouths to clear clogged spray nozzles. The pyrethroids are also absorbed via inhalation; however, in these same sprayers, inhalation was not found to be a clinically significant route of exposure as analyzed by breathing zone assays.²⁷ The pyrethroids are not volatile compounds, so inhalation is always due to powders or sprayed mists, and mucosal and pulmonary toxicity may be due to hydrocarbon solvent vehicles. Systemic absorption and resultant effects may follow massive exposures, such as occurs in enclosed spraying or other extreme conditions.

Distribution. The pyrethroids and pyrethrins are lipophilic and as such are rapidly distributed to the central nervous system. Because they are rapidly metabolized, there is no storage or bioaccumulation, which limits chronic toxicity.^{46,45}

Metabolism. Natural pyrethrins are readily metabolized by mammalian microsomal enzymes, and hence are essentially nontoxic to humans. They can induce CYP3A and CYP2B isoforms in vitro in human cultured hepatocytes, but clinical significance is doubtful.¹¹⁰

The synthetic pyrethroids are readily metabolized in animals and humans by hydrolases and the CYP microsomal system. The metabolites are of lower toxicity than the parent compounds.¹⁴⁰ Piperonyl butoxide, a P-450 inhibitor, enhances the potency of pyrethrins and pyrethroids 10- to 300-fold to target insects. It is often added to insecticide preparations to ensure lethality, as the initial “knock down” effect of a pyrethroid alone is not always lethal to the insect.⁴⁵ Testing of piperonyl butoxide on antipyrine metabolism (measure of CYP enzyme function) in humans at a dose exceeding 50 times that received in all-day confined space pesticide spraying revealed no effect on this enzyme system in humans.¹¹¹

Elimination. There is no evidence that the pyrethroids undergo enterohepatic recirculation. Deltamethrin disappeared from the urine of exposed workers within 12 hours, and fenvalerate disappeared within 24 hours.²⁷ Parent compounds, and metabolites of the pyrethroids, are found in the urine.¹¹⁶ The most commonly assayed metabolites are 3-PBA (3-phenoxybenzoic acid, a nonspecific metabolite of multiple pyrethroids), cis-DCCA (cis-3-{2,2-dichloroethenyl}-dimethyl cyclopropane carboxylic acid, a metabolite of cis-permethrin, cypermethrin, and cyfluthrin), trans-DCCA (trans-3-{2,2-

dichloroethenyl}-dimethyl cyclopropane carboxylic acid, a metabolite of trans-permethrin, cypermethrin, cyfluthrin), and Br2CA (3-{2,2-dibromovinyl}-2,2-dimethylcyclopropanecarboxylic acid, a metabolite of deltamethrin). The metabolite CDCA (chrysanthemumdicarboxylic acid) is also a nonspecific metabolite of natural pyrethrin I and the synthetic pyrethroids allethrin, resmethrin, and tetramethrin^{87,149} Monitoring of these metabolites is used in population-based studies for pesticide exposures. However, a recent review revealed that commonly assayed pyrethroid metabolites also occur in the environment from natural degradation. Therefore, the detection of these metabolites in the urine may be from a subject's exposure to the parent compound or from its metabolite in the environment

Pathophysiology

Like DDT, pyrethrins and pyrethroids prolong the activation of the voltage-dependent Na⁺ channel by binding to it in the open state, causing a prolonged depolarization, as evidenced by an extended tail current seen with squid axon voltage clamp experiments.^{98,99} Indeed, DDT and pyrethrin/pyrethroids bind to the same site on insect Na⁺ channels, and resistance to one class causes cross-resistance to the other class as well.¹⁰² The voltage-sensitive Na⁺ channel binding is responsible for the insecticidal activity and the toxicity of the pyrethroids to nontarget species. Natural pyrethrins and type I synthetic pyrethroids induce repetitive or "burst discharges" following a single stimulus because they hold the Na⁺ channel in its open state for shorter periods. The actual amplitude of the tail current is determined by the concentration of the pyrethroids, regardless of type. Type II pyrethroids cause the Na⁺ channel to remain open longer and allow a prolonged period of depolarization of the resting membrane potential, causing a longer duration of the tail current.^{143,161} Type II pyrethroids are thus more potent and lead to significant after-potentials and eventual nerve conduction block. The mammalian voltage-dependent Na⁺ channel, unlike the insect, has many isoforms, and may help explain the relative resistance in mammalian species. Different pyrethroids have varied effects on these mammalian Na⁺ channels, and the effects are not additive, and in fact may be antagonistic. Structure-activity relationship is important as well because some pyrethroid trans isomers at the ester linkage are not insecticidal, but the cis isomers are, and some isomers are insecticidal but lack mammalian toxicity because of this isomeric specificity.¹⁴⁰

Pyrethroids also have activity at certain isoforms of the voltage-sensitive calcium channel, which may explain the neurotransmitter release that occurs in pyrethroid intoxication. Additionally, pyrethroids block voltage-sensitive chloride channels in test animals, producing the salivation as part of the CS syndrome. These effects may contribute to enhanced CNS toxicity¹⁴⁰ and are likely responsible for the choreoathetosis that occurs in animal models of severe type II poisonings.¹¹⁴ Some studies show some interference of the type II pyrethroids with the GABA_A-mediated inhibitory chloride channels, but only in high concentrations.^{28,97} Antagonism of the GABA_A chloride channels likely has a significant role in human pyrethroid exposures and probably contributes to the seizures following severe poisoning by type II agents.^{97,114} The pyrethroids may also act at the peripheral benzodiazepine receptor, as evidenced by decreased salivation in test animals when this receptor was blocked. The clinical significance of this is currently unknown.¹³

Natural pyrethrins and type I pyrethroids have a negative temperature coefficient, similar to DDT, and are more selectively toxic to non- warm-blooded target species, but also less effective at warmer environmental temperatures. Type II pyrethroids have a positive temperature coefficient, which makes them more insecticidal at higher ambient temperatures, and thus more useful in agricultural applications.^{97,164} However, this may also partly explain the greater toxicity of type II pyrethroids to warm-blooded species as compared to type I.⁹⁷

Clinical Manifestations

Pyrethrum probably has an LD₅₀ of well over 1 g/kg in humans, as extrapolated from animal data. Most cases of toxicity associated with the pyrethrins are the result of allergic reactions.^{107,165} Theoretically, those at highest risk for allergic reactions would be patients who are sensitive to ragweed pollen, 50% of whom may cross-react with chrysanthemums (ragweed and chrysanthemum are in the same botanical family). These allergic reactions are postulated to be due to residual natural components present in the extracts.¹¹⁶ However, recent reviews have cast some doubt on this explanation. First, there have been only four cases of life-threatening respiratory reactions reported in the literature, three of which were in known asthmatics.¹¹¹ Second, the presence of residual natural proteins is unlikely, as the purification procedures would allow little, if any, residuals.⁵⁹ Third, most reported cases of contact urticaria have been erroneously classified as type I hypersensitivity reactions.⁵⁹ The synthetic pyrethroids can cause histamine release in vitro⁴² but generally do not induce IgE-mediated allergic reactions.¹⁷

In animals, type I pyrethroid poisoning most closely resembles that of DDT, with extensive tremors, twitching, increased metabolic rate, and hyperthermia. Excluding the rare possibility of skin irritation or allergy, the type I pyrethroids are unlikely to cause systemic toxicity in humans. It has been shown experimentally that pyrethroids have greater than 1000-fold more affinity for insect Na⁺ channels than for those of mammals, explaining their low toxicity in higher life forms. This

selectivity, along with the negative temperature coefficient and slower insect metabolism, combines to make the type I pyrethroids approximately 15,000 times more toxic in insects than humans.⁹⁹ The type II pyrethroids are generally more potent and cause profuse salivation, ataxia, coarse tremor, choreoathetosis, and seizures in animals. In humans, poisoning with type II pyrethroids can cause paresthesias (secondary to Na⁺ channels effects in cutaneous sensory nerves after topical exposure),⁸⁵ salivation, nausea, vomiting, dizziness, fasciculations, altered mental status, coma, seizures, and acute lung injury.⁶⁸ A review of more than 500 cases of acute pyrethroid poisoning from China highlights some similar manifestations between a massive acute type II pyrethroid overdose and an organic phosphorus compound overdose. However, serious atropine toxicity and death has resulted when poisoning from a type II pyrethroid was mistaken for an organic phosphorus compound, and treatment was directed at these seemingly muscarinic signs.⁶⁸ Features such as acute respiratory distress syndrome may be caused by solvents and surfactants present in the agricultural products.⁸ Although the type II pyrethroids contain a cyanide moiety, cyanide poisoning does not occur, and cyanide antidotal therapy is not indicated.

Most significant unintentional exposures are dermal, especially in occupational settings, and local symptoms predominate in the majority of these cases. Systemic effects from insecticidal sprayings have been reported from wind drift or inappropriate handling, and the more potent type II pyrethroids predominate in case reports. An exposure of workers possibly affected by wind drift from a mixture of 32 ounces of the type II pyrethroid cyfluthrin mixed with 18.5 gallons of petroleum oil and 1800 gallons of water was reported in California in 2006. Spraying occurred in a citrus grove, and 23 female workers in an adjacent vineyard were possibly exposed. These workers complained of a “chemical” odor and felt ill with headaches, nausea, eye irritation, weakness, anxiety, and shortness of breath. They were all evaluated in local EDs and discharged home. Despite the fact that no cyfluthrin was detected on these²⁵ workers’ clothing or on foliage in the field where they were alleged to have been exposed, the report concluded that cyfluthrin was the cause; no estimate of the contribution of the petroleum vehicle to the symptoms was posited.²⁵ The predominant feature after significant cutaneous exposures is local paresthesias in the areas of skin contact, due to Na⁺ channel effects on cutaneous sensory nerves. Local skin irritation was seen in up to 10% of workers spraying pyrethroid insecticides, but it is rarely seen after medicinal use of the pyrethroid creams and shampoos. Ocular contact causes more severe symptoms, including immediate pain, lacrimation, photophobia, and conjunctivitis.¹³

Intentional ingestions represent the most serious exposures, due to the higher doses involved and the greater exposures to vehicles and solvents. However, a study of 48 cases of permethrin/xylene/surfactant mixtures (38 were suicidal ingestions) revealed that mild GI signs and symptoms predominated (73%: sore throat, mouth ulcerations, dysphagia, epigastric pain, vomiting). Pulmonary signs and symptoms were documented in 29%, and eight patients (including one death) had aspiration pneumonia. Thirty three percent had CNS symptoms: confusion (13%), coma (21%), and seizures (8%). The involvement of the central nervous system and lungs were less common, but clinically more significant.¹⁷² The relative contributions of the 70% xylene and 10% surfactant were likely responsible for much of the GI and pulmonary effects, though it was not discussed in the report.

Chronic Exposures

Since the pyrethroids are rapidly metabolized and are not biopersistent compounds, they have not been shown to cause cumulative toxicity. A single case of motor neuron disease resulted from heavy daily inhalation exposure to pyrethroid mixtures in a combined space for 3 years, which resolved after exposure ceased.⁴³ Some investigators have expressed concerns regarding possible neurotoxicity of the pyrethroids. However, a recent review noted that regulatory studies in multiple species have shown no evidence supporting gross neurodevelopmental toxicity or adult neuronal loss in man.¹¹⁴ In Germany, a unique situation exists where numerous civil lawsuits allege multiple chemical sensitivity (MCS) was caused by pyrethroid exposures. Scientific study of this phenomenon yields no scientific data to support this contention,¹¹ and the controversy is fueled by civil litigation, popular media sensationalizing, and subsequent public fear.⁵

Treatment

Initial treatment should be directed toward skin decontamination, as most poisonings occur from exposures by this route. Patients with intentional oral ingestions of a type II pyrethroid should be treated with a single standard dose of AC, provided the diluent of the pyrethroid does not contain a petroleum solvent. Contact dermatitis and acute systemic allergic reactions should be treated in the usual manner, utilizing histamine blockers, corticosteroids, and β -adrenergic agonists as clinically indicated.

Treatment of systemic toxicity is entirely supportive and symptomatic because no specific antidote exists. Benzodiazepines should be used for tremor and seizures. Topical vitamin E oil (dl- α -tocopherol) is especially effective in preventing and treating cutaneous paresthesias due to topical pyrethroid exposures.^{13,116}

INSECT REPELLENTS

Mosquitoes transmit more diseases to humans than any other biting insect. Worldwide, more than 700 million people are infected yearly by mosquito bites that transmit such diseases as malaria, viral encephalitis, yellow fever, dengue fever, bancroftian filariasis, and epidemic polyarthritis. Novel approaches to mosquito control also includes impregnation of indoor house paints with various insecticides (organic phosphorus compounds) and insect growth regulators. The WHO estimates that in 2010 there were about 219 million malaria cases and an estimated 660,000 malaria deaths worldwide.⁶ In the United States, eight people died from West Nile Virus (WNV) in NYC in 1999, and by January 2005, the virus, carried by mosquitoes from infected birds, had spread to all lower 48 states. Therefore, mosquito repellants have become important public health tools, and DEET has been the time-tested primary weapon for the past five decades. However, much controversy continues to surround DEET despite a remarkable safety profile with over a half-century of global use by billions of people. A growing trend in the United States and many western cultures has been a chemophobia against synthetic products like DEET. Many people favor plant-based “natural” or “organic” repellents, paralleling the increasing consumer preference for natural or organic foods. Several xenobiotics are proposed, but thus far few have been shown by objective blinded studies to even approach the efficacy of DEET, much less surpass it. Numerous comprehensive reviews of the subject have demonstrated superiority of DEET in most cases, and it remains the insect repellent standard by which all others are measured (Table 114–3).

TABLE 114–3 Comparative Efficacy and Toxicity of Commonly Available Insect Repellents

<i>Insect Repellent</i>	<i>EPA Approval</i>	<i>EPA Toxicity Rating^a</i>	<i>Efficacy in Lab and Field studies^b</i>	<i>Notes</i>
DEET	1957 (1980)	III	Most efficacious in lab and field studies; proven protection against ticks and mosquitoes	>50 years of experience, billions of users 10%–30% soln: safe, effective when used as directed
Picaridin (Bayrepel)	2001	IV	20% soln: Lab: Equivalent to DEET Field: Essentially equivalent to DEET	All studies done on 20% picaridin; no studies done with 7% US formula Recommended by CDC as a DEET alternative
IR3535 (Substituted β amino acid)	1999	IV	Lab: Inferior to DEET Field: None available	Recommended by CDC as a DEET alternative
Oil of Lemon Eucalyptus (p-menthane diol)	2000	IV (I, ocular)	Equivalent to DEET for mosquitoes; not tested for tick bite prevention	Recommended by CDC as a DEET alternative
BioUD (2-undecanone)	2007	IV	Lab: Equivalent to 7% DEET Field: Equal to 25% and 30% DEET	Studies performed by patent holders and developers of IR, no impartial evidence
Citronella oil	1948	IV	Lab study: Ineffective	Candles only provide some repellency when within 1 meter

^aEPA Acute Toxicity Ratings: Category I = very highly or highly toxic; Category II = moderately toxic; Category III = slightly toxic; Category IV = practically nontoxic. ^bLab tests: arm in cage studies for mosquito repellency; Field studies: actual biting or tick attachment assays in natural conditions.

DEET

The topical insect repellent, N,N-diethyl-3-methylbenzamide (DEET, former nomenclature N,N-diethyl-meta-toluamide), was patented by the US Army in 1946 and has been commercially marketed in the United States since 1956. Currently, it is used worldwide by more than 200 million persons annually. The EPA estimates that 38% of the US population uses DEET each year. Despite the current search for alternatives, DEET is still the most effective repellent available and has the most clinical toxicity information.^{56,57}

DEET can be purchased without prescription in concentrations ranging from 5% to 100%, and in multiple formulations of solutions, creams, lotions, gels, and aerosol sprays. Mosquitoes are attracted to their hosts by temperature and chemical attractants, principally CO₂ and lactate. The mechanism by which DEET repels insects was thought to be due to some interference with the chemoreceptors that detect lactic acid and CO₂.^{56,112} However, recent work has demonstrated that DEET itself is actually detected by the mosquito’s olfactory receptors and repels them independently of whether the normal physical or chemical attractants are present.¹⁵¹ DEET formulations can feel greasy or sticky and can dissolve or damage some plastics (eyeglass frames, watches) and synthetic fabrics.

Toxicokinetics

DEET is extensively absorbed via the gastrointestinal tract.¹⁵⁹ Skin absorption is significant, depending on the vehicle and the concentration. Transdermal absorption of 30 to 45% DEET in ethanol is significantly higher than 100% DEET solution

in an in vitro human skin model.¹⁴⁷ This has led to development of microencapsulated liposphere formulas and polyethylene glycol-based solutions that reduce absorption and increase repellent time and efficacy in animal models.⁴⁴

DEET does not bind to stratum corneum, and only 0.08% or less of a dose remains in the skin 8 hours after application.¹¹² DEET is lipophilic, and skin absorption usually occurs within 2 hours, although it is eliminated from plasma within 4 hours. The volume of distribution is large, in the range of 2.7 to 6.2 L/kg in animal studies. DEET is extensively metabolized by oxidation and hydroxylation by the hepatic microsomal enzymes, primarily by the isozymes CYP2B6, 3A4, 2C19, and 2A6.¹⁵⁹ DEET is excreted in the urine within 12 hours, mainly as metabolites, with 15% or less appearing as the parent compound.^{57,112}

DEET toxicity reports and studies have been extensively reviewed in terms of acute and chronic toxicity. It has been found safe for use in pregnant and lactating women⁸²; it was found to have no specific target organ toxicity or oncogenicity in any observed rat, mouse, or dog studies¹³⁶; and chronic DEET exposure together with other insecticides showed no increased cancer risks.¹⁰⁶

Pathophysiology

The exact mechanism of DEET toxicity is unknown. Recent reviews of adverse reactions to DEET reported 26 cases with major morbidity including encephalopathy, ataxia, convulsions, respiratory failure, hypotension, anaphylaxis, or death, particularly after ingestion or dermal exposure to large amounts.^{22,57,104,105,154,160} These primarily neurologic adverse reactions occurred mainly in children, and most involved prolonged use and excessive dosing beyond what is currently recommended. One fatal case involved a child who was known to be heterozygous for ornithine carbamoyl transferase (OCT) deficiency, and death was because of a Reye-like syndrome with hyperammonemia. This child had experienced prior episodes of hyperammonemia unrelated to DEET use, and DEET does not appear to affect, or be affected by, OCT activity in humans.¹⁰⁴ Currently, there is no evidence that enzyme polymorphism affects DEET metabolism or influences individual susceptibility to toxicity.

Although single, large, acute oral doses (1–3 g/kg) in rats produced seizures and CNS damage,^{134,135} smaller acute doses (500 mg/kg and less) and chronic multigenerational dosing in another rat study produced no obvious toxicity.¹³⁴ Teratogenicity studies in rats and rabbits failed to demonstrate toxicity except at the highest doses,^{136,171} and DEET was not found to be carcinogenic.^{112,136} In view of the billions of applications, the number of reports of toxicity appears exceedingly small and suggests a remarkably wide margin of safety.^{57,65,104,105,120,150,160}

Clinical Manifestations

Most calls to poison control centers regarding DEET exposures involve minor or no symptoms, and symptomatic exposures occur primarily when DEET is sprayed in the eyes or inhaled.¹⁶⁰ Except for suicidal ingestions, most serious reactions consist of seizures in children overexposed via the dermal route; in fact, some of these cannot be definitely attributed to DEET.^{65,104} Most symptoms resolve without treatment, and the majority of patients with serious toxicity recover fully with supportive care. A case report of severe poisoning developed in a man with extreme exposure. He used 30% DEET on his entire body several times daily for a prolonged time period, with an entire bottle used the day prior to admission. He developed weakness and nausea which progressed to confusion and shortness of breath. Metabolic acidosis, elevated lactate concentration, acute kidney injury requiring hemodialysis, and worsening weakness requiring mechanical ventilation developed. His blood DEET concentration was 130 ppb (µg/L). No seizures developed, and he experienced a full neurological recovery after a prolonged hospitalization.¹¹⁷

Treatment

Patients with DEET exposures are treated with supportive care aimed at primarily neurologic symptoms. In cases of dermal exposures, skin decontamination should be a priority to prevent further absorption. Patients with intentional oral ingestions should receive a single dose of AC if clinically indicated.

An extensive review of the safety risk of DEET repellent use confirms its safe use for all populations when used according to labeling guidelines.¹⁵⁰ Despite its good safety profile, avoiding the overuse of DEET seems prudent. The American Academy of Pediatrics (AAP) revised its recommendations for insect repellent (IR) use due to the emergence of WNV infections (prior recommendations were for use of products with DEET <10%).¹³⁷ They found that DEET-containing products are the most effective mosquito repellents available and are also effective against a variety of other insects, including ticks. IR with a DEET concentration from 10% to 30% (the maximum recommended for children) appear to be equally safe when used according to the directions on the product labels. The safety of DEET does not appear to relate to differences in these concentrations, and higher concentrations have longer durations of effects.¹ As indicated in the AAP handbook, repellents are not recommended for children younger than 2 months of age.²

The higher concentrations prolong the repellency period, but there is a plateau at about 50% DEET concentration, and about 6 hours may be the maximum protection time from any single application. Newer, longer-acting DEET formulations in lipids or polymers cause the DEET to evaporate more slowly, which affords protection for > 6 hours and also less systemic absorption.^{79,131} Since the lower concentrations recommended for children last approximately 2 hours, frequent reapplication is usually unnecessary. Since mosquitoes are most active for a few hours preceding and following dusk, DEET should be promptly washed off the child's skin when protection is no longer needed. Soaking the skin is not more effective and may contribute to toxicity. DEET should be applied only to exposed skin. One should avoid abraded skin or skin with rashes. Care should be taken to avoid exposure to eyes and sensitive skin areas. Avoid use on children's hands, so that the child does not wipe on eyes, mouth, genitalia, and so on. Adults should apply DEET to their own hands and then wipe onto the child's face, rather than spraying onto a child's face.

DEET combination products which include sunscreen should not be used together for mosquito repellency, since these combination products mutually enhance the percutaneous absorption of each component in both a porcine in vivo study⁷⁷ and in an in vitro mouse skin model.¹²⁴ Since mosquitoes are most active near dusk, there is clearly no need for the sunscreen component when repelling mosquitoes. These new combination products may be useful for tick repellency, however. Other options for protection include mechanical means, such as mosquito netting, as well as permethrin-impregnated clothing for tick prevention.

Newer Insect Repellents

The efficacy of any drug, treatment, or repellent is directly related to compliance with the treatment. Despite its demonstrated efficacy and safety, many people view chemical insect repellents such as DEET as potentially harmful and avoid their use. Several survey results in the United States and Canada revealed that 56% of people believe repellents are likely to be harmful to children, and 45% believed insect repellents are likely to sicken adults.¹⁶⁷ This has led to an intense search for effective alternatives to DEET-based repellents. Although their efficacy is not superior to DEET, their safety is likely at least equivalent to that of DEET, since the most recent data from NPDS revealed out of more than 1300 reported exposures, most reported no or minor effects.¹⁶

Picaridin (Bayrepel, KBR3023; CASRN: 119515-38-7). Picaridin (chemical name: 2-{2-hydroxyethyl}-1-piperidinecarboxylic acid 1-methylpropyl ester) is also known as Bayrepel and KBR 3023 in Europe. It is a piperidine derivative and has low acute oral, dermal, and inhalation toxicity. The EPA classifies it as Toxicity Category IV for acute inhalation toxicity and primary dermal irritation, the lowest rating available (Class III for oral ingestion). It is not a dermal sensitizer, and no developmental toxicity was observed in chronic animal feeding studies. It was also not shown to be mutagenic in a battery of tests and is not considered carcinogenic.⁴⁷ Picaridin is nearly as efficacious as DEET in comparison studies of the 20% solution used in Australia and Europe, but unfortunately no studies have compared the 7% formula marketed in the United States (Cutter Advanced; Avon Skin So Soft with Picaridin). Since duration of protection is generally related to concentrations of the repellent (clearly shown with DEET), it would be reasonable to assume the 7% US formula would not have as long a duration of effect. A comprehensive MedLine search performed in February 2013 revealed no reports of human toxicity of picaridin insect repellents

2-Undecanone (BioUD; Methyl Nonyl Ketone; CAS#: 112-12-9). A newly formulated natural repellent, 2-undecanone, was approved for use as an IR by the EPA in 2007 and is known by the brand name of BioUD. Its active ingredient is derived from the wild tomato plant *Lycopersicon hirsutum* Dunal f *glabratum* C. H. Mull.¹⁶⁷ 2-Undecanone (also known as methyl nonyl ketone) was originally registered in 1966 as a dog and cat repellent and training aid and as an iris borer deterrent. It received EPA approval as a topical insect repellent in 2007. The EPA RED documents that in studies using laboratory animals, methyl nonyl ketone exhibited no toxicity via the oral and inhalation routes and was placed in Toxicity Category IV. Methyl nonyl ketone was slightly toxic (Toxicity Category III) for dermal toxicity, eye irritation, and dermal irritation and was a weak dermal sensitizer. Since it has a long history of safe use, is from a natural source, and is an approved food additive, it is considered essentially nontoxic. Methyl nonyl ketone is currently found in only one insect repellent in the form of both a lotion and a spray known as HOMS BiteBlocker Insect Repellent.⁵¹ The manufacturer lists a nonpublished study on its website of a field test showing protection from mosquito bites surpassing that of a DEET 30% at 6 hours, and equivalent at 4 hours.⁶⁹ A 2008 study done by the inventors and patent holders showed it was only as efficacious as lower DEET concentration products in laboratory arm-in-cage trials, but field trials revealed efficacy equivalent to 25% to 30% DEET formulations.¹⁶⁷ A comprehensive MedLine search performed in February 2013 revealed no reports of human toxicity of 2-undecanone insect repellents

Oil of Lemon Eucalyptus (PMD; p-menthane-3,8-diol; CAS 42822-86-6). Oil of Lemon eucalyptus occurs naturally in the lemon eucalyptus plant (*Eucalyptus citriodora* also known as *Corymbia citriodora*). It is marketed in the USA under the brand name "OFF! Botanicals Insect Repellent®". The natural oil can be extracted from the eucalyptus leaves and twigs; commercially the active ingredient, p-menthane-3,8-diol (PMD), is chemically synthesized, and is structurally similar to menthol. In its pure form, it is a solid at room temperature, and has a faint mint-like odor. PMD is placed into Toxicity Category IV for acute oral toxicity, dermal toxicity and skin irritation, and Toxicity Category I for eye irritation (Toxicity

Category II for the end-use product). It is not a skin sensitizer. The EPA has determined that there is reasonable certainty of no harm to the U.S. population or subpopulations, including infants and children, as the result of the uses of PMD to formulate insect repellents.⁴⁸ This compound is not to be confused with eucalyptus oil, a toxic essential oil containing 1,8 cineole (CAS#470-82-6), which has no insect repellent properties. A comprehensive MedLine search performed February 2013 revealed no reports of human toxicity of PMD insect repellents.

Oil of Citronella. Plant-derived essential oil products are considered minimum-risk pesticides and are exempt from Environmental Protection Agency registration under Section 25(b) of the Federal Insecticide Fungicide and Rodenticide Act. Oil of Citronella has been used for over 50 years as an insect repellent and as an animal repellent in candles and topical skin products. These products, which have little efficacy, are not expected to cause harm to humans, pets, or the environment when used according to the label.⁵² A comprehensive MedLine search performed in February 2013 revealed no reports of human toxicity of citronella-containing insect repellents

Legal Standards for an Insecticide Label

The Federal Insecticide, Fungicide, and Rodenticide Act of 1962 established criteria for a “signal word” on an insecticide label, which implies the degree of toxicity based on an oral LD₅₀. Also, the label on the original container of these products is usually instructive and should always be brought to the medical facility (Table CS9–1).

SUMMARY

- Organic chlorine insecticide agricultural use has largely been eliminated in the United States and Europe but remains a problem in the developing countries. DDT remains an important tool for control of malaria vector mosquitoes. These xenobiotics classically cause neurological toxicity (tremors, seizures) when ingested.
- Pharmaceutical use of lindane for topical ectoparasitic infestations has decreased greatly in favor of less toxic permethrin preparations. Lindane is still available in most of the United States.
- Pyrethroid insecticides are the most commonly used insecticides for home use and have a lower order of toxicity than organic chlorine or organic phosphorus insecticides. The Type II pyrethroids are more potent and can cause systemic toxicity (CNS, pulmonary) when ingested, but toxicity may be due to solvents and surfactants in the formulations.
- DEET containing insect repellents are still the most efficacious formulas and have many years of safe use in billions of people worldwide when used as directed. Neurological toxicity has been described with extreme exposure situations.
- Some newer insect repellents have efficacy approaching that of DEET, and few reported toxicities. As these newer repellents become more commonly used, it is not expected that significant toxicities will be manifested.

115 SODIUM MONOFLUOROACETATE AND FLUOROACETAMIDE

Fermin Barrueto Jr.

HISTORY AND EPIDEMIOLOGY

Sodium monofluoroacetate (SMFA) occurs naturally in plants native to Brazil, Australia, and South and West Africa (eg, gifblaar {*Dichapetalum cymosum*}).¹¹ The highest concentration (8.0 mg/g) is found in the seeds of a South African plant, *Dichapetalum braunii*.¹¹ In the 1940s, SMFA was released as a rodenticide (CAS No. 62-74-8) and assigned the compound number 1080, which was registered as its trade name. Fluoroacetamide, a similar pesticide, is known as Compound 1081. These compounds are widely effective as poisons against most mammals and some amphibians.²⁶ Both products were banned in the United States in 1972, except to protect sheep and cattle from coyotes. Collars embedded with SMFA are placed around the neck of livestock, the typical point of attack for coyotes.

Sodium monofluoroacetate is used extensively in New Zealand and Australia to control the possum population and other animal species considered pests that have no natural predators. Its continued use is extremely controversial, but following a recent review of the ramifications of the use of the compound, the government of New Zealand retained both the aerosolized and collar applications. Reported cases of human poisoning with SMFA are uncommon and the epidemiology is poorly understood. There have been only 65 reported cases from 1999 to 2010 with no deaths in the National Poisoning Database System of the American Association of Poison Control Centers ([Chap. 136](#)).

TOXICOKINETICS AND TOXICODYNAMICS

Sodium monofluoroacetate is an odorless and tasteless white powder with the consistency of flour. When it is dissolved in water, it is said to have a vinegarlike taste. Sodium monofluoroacetate and fluoroacetamide (CAS No. 640-19-7) are well absorbed by the oral and inhalational routes.^{10,11,12,27} Detailed toxicokinetic data are lacking in humans, but in sheep, up to 33% of an ingested dose is excreted unchanged in the urine over 48 hours. Glucuronide and glutathione conjugates have been isolated.¹¹ Substantial defluorination is not thought to occur in vivo. The serum half-life is estimated to be 6.6 to 13.3 hours in sheep.¹⁰ Sodium monofluoroacetate has an LD₅₀ of 0.07 mg/kg in dogs.¹⁹ The oral dose thought to be lethal to humans is 2 to 10 mg/kg.³

PATHOPHYSIOLOGY

Sodium monofluoroacetate, a structural analog of acetic acid ([Fig. 115–1](#)), is an irreversible inhibitor of the tricarboxylic acid cycle ([Fig. 13–3](#)). Monofluoroacetic acid enters the mitochondria, where it is converted to monofluoroacetyl-coenzyme A (CoA) by acetate thiokinase. Mitochondrial citrate synthase is then joined with the monofluoroacetyl-CoA complex with oxaloacetate to form fluorocitrate. Fluorocitrate then covalently binds aconitase, preventing the enzyme from any further metabolic activity in the tricarboxylic acid cycle.¹⁷ Thus, fluorocitrate acts as a “suicide inhibitor” of aconitase, producing a biochemical dead end. The net toxicity caused by fluorocitrate results from the increase in tricarboxylic acid cycle substrates proximal to inhibition of aconitase and the depletion of substrates distal to the step catalyzed by aconitase. This inhibition of aconitase impairs energy production, leading to anaerobic metabolism and metabolic acidosis with an elevated lactate concentration. Additionally, other tricarboxylic acid cycle intermediates increase in concentration, contributing to the toxicity. α -Ketoglutarate depletion, caused by the lack of isocitrate, leads to glutamate depletion since α -ketoglutarate is a precursor of glutamate synthesis. Glutamate depletion leads to urea cycle disruption and ammonia accumulation. Impaired fatty acid oxidation leads to ketosis. Excess citrate binds to divalent cations such as calcium causing hypocalcemia.

FIGURE 115–1. Structural similarities among acetyl-CoA, sodium monofluoroacetate, and fluoroacetamide.

Disruption of the tricarboxylic acid and urea cycles affects every system in the human body, but the most consequential effects occur in the central nervous system and the cardiovascular system. Fluoride toxicity from enzymatic defluorination of sodium monofluoroacetate and fluoroacetamide does not occur substantially *in vivo* and is of minor significance.

CLINICAL MANIFESTATIONS

The majority of the clinical experience with SMFA is associated with intentional self-poisoning; fluoroacetamide poisoning is presumed to have a similar presentation.^{9,16,18,29} Most patients develop symptoms within 6 hours after exposure. In the largest case series of 38 Taiwanese patients who ingested SMFA, 7 died.⁶ The most common clinical findings recorded at the time of emergency department (ED) presentation were nausea and vomiting (74%), diarrhea (29%), agitation (29%), and abdominal pain (26%).⁶ The mean time to presentation to the hospital was 10.9 ± 5.7 hours for those who died and 3.4 ± 0.6 hours for the survivors. All deaths occurred within 72 hours of admission to the hospital. The presence of respiratory distress or seizures was a poor prognostic indicator of death. All seven patients who died had systolic blood pressures less than 90 mm Hg on presentation to the ED, a finding noted in only 16% of the survivors.⁶

In a case series involving two patients, invasive hemodynamic monitoring revealed persistent low systemic vascular resistance and increased cardiac output despite adequate fluid resuscitation.⁷ The authors theorized that the cardiovascular response may have been triggered by ATP depletion and inhibition of gluconeogenesis.⁷ Anaerobic metabolism, mitochondrial inhibition, and sensitivity of the vasculature to SMFA are also confounding factors.

The initial neurologic manifestations consist of agitation and confusion with progression to seizures. Neurologic sequelae such as cerebellar dysfunction may be permanent.^{30,15} One report describes a 15 year-old girl who survived an initial exposure to SMFA but later developed cerebellar dysfunction and cerebral atrophy, demonstrated by brain computed tomography.³⁰ QT interval prolongation, premature ventricular contractions, ventricular fibrillation, ventricular tachycardia, and other dysrhythmias are documented.⁶ SMFA has negative inotropic effects, except in one case report that described episodic hypertension.²⁵ Signs and symptoms associated with severe poisoning are seizures, respiratory distress, and hypotension.

DIAGNOSTIC TESTING

The presence of SMFA and fluoroacetamide can be confirmed in the blood and urine with gas chromatography–mass spectrometry and thin-layer chromatography.^{1,5,20} Simultaneous analysis for other rodenticides that can induce seizures, for example, fluoroacetamide and “tetramine,” has been performed by gas chromatography in China, where exposure to these xenobiotics is more probable.^{2,4,31} Like tetramine, SMFA is considered a potential weapon of mass destruction.¹³ An elevated serum citrate concentration has been proposed as a useful marker for exposure to SMFA.⁴ However, none of these studies can be performed in a clinically relevant period. A combination of history, signs, symptoms, and common laboratory tests can assist with the diagnosis.

Hypokalemia, anion gap metabolic acidosis, and an elevated creatinine concentration⁸ are associated with severe poisoning but are very nonspecific.⁶ The predominant electrolyte abnormality will be hypocalcemia, although hypokalemia can result from acute kidney injury and gastrointestinal losses. Creatinine, liver enzyme, and bilirubin concentrations may also be elevated as a result of multisystem organ toxicity. Ketones may be present in urine and serum. A complete blood

cell count may reveal leukocytosis. An electrocardiogram is valuable in the diagnosis of SMFA exposure; a prolonged QT interval, atrial fibrillation with a rapid ventricular response, ventricular tachycardia, and other dysrhythmias may be present.^{6,28} An initial computed tomography scan of the brain may be normal, but subsequent scans may reveal cerebral atrophy.³⁰ Diffusion weighted magnetic resonance imaging (MRI) has shown reversible symmetric high signal intensity in the cerebellar peduncles, corpus callosum, internal capsules, and corona radiata in an SMFA poisoned patient with a sublethal ingestion. MRIs were performed on the day of ingestion and 7 days later.¹⁵ Brain single photon emission computed tomogram (SPECT) was also normal 14 days later.

TREATMENT

Initial decontamination should include removal of clothes and cleansing of skin with soap and water. Because there is no proven antidote for SMFA or fluoroacetamide poisoning, orogastric lavage should be considered for exposed patients who present to the ED prior to significant emesis. Appropriate patients should receive 1 g/kg of activated charcoal (AC) orally. A rat study showed that colestipol is more effective than AC in binding SMFA.²¹ By extension, it seems reasonable to consider the use of colestipol, if available, for the treatment of life-threatening exposures in humans, although there are no human data to support this therapy. A suggested initial dose would be 5 g.

In a cat model, glycerol monoacetate (monacetin) at a dose of 0.5 mL/kg every 30 minutes prolonged survival. In this context, monacetin functions as an acetate donor for ultimate incorporation into citrate in place of fluoroacetate.²⁹ Both ethanol and glycerol monoacetate are converted to acetyl-CoA and compete with monofluoroacetyl-CoA for binding of citrate synthase. This may prevent the “suicide-inhibition” of aconitase, subsequent increase in citrate, and the formation of the toxic metabolite fluorocitrate.²⁹ Availability of monacetin for human use is limited, and appropriate human dosing is unknown.

Ethanol has been used in human cases, although the appropriate dose is unknown and there is not enough evidence to support its use as a single antidote.^{6,7,24} A reasonable therapeutic dose is the amount of ethanol required to obtain and sustain an ethanol serum concentration of 100 mg/dL (Antidotes in Depth: A31). One intriguing case report involves a patient who ingested 240 mg of SMFA (typically a lethal dose) mixed with a Taiwanese wine (30% ethanol) and survived.⁶ It is possible that the ethanol decreased or delayed the toxicity of SMFA.

In a mouse model, use of a combination of calcium salts, sodium succinate, and α -ketoglutarate improved survival.²² The rationale of using these antidotes is to provide tricarboxylic acid cycle intermediates distal to the inhibited aconitase in an attempt to improve energy production. These antidotes were not effective unless calcium was coadministered, emphasizing the importance of replenishing electrolytes, particularly the divalent cations that are chelated by citrate.^{14,28,23}

If a patient develops hypotension and shock, rapid administration of intravenous 0.9% NaCl should be followed by a vasopressor, such as norepinephrine or vasopressin. Supportive care, correction of electrolyte abnormalities (especially calcium and potassium), ethanol infusion, and monitoring for dysrhythmias (prolonged QT interval) and seizures are the practical mainstays of treatment.

SUMMARY

- Sodium monofluoroacetate and fluoroacetamide are potent pesticides that inhibit the tricarboxylic acid cycle, disrupting cellular energy production.
- Patients who are exposed to SMFA typically present with nausea, vomiting, agitation, and abdominal pain, which may be followed by hypotension, respiratory distress, shock, seizures, and death.
- Lactate accumulation, hypokalemia, hypocalcemia, metabolic acidosis, and elevation of serum creatinine also occur.
- Treatment of SMFA and fluoroacetamide poisoning largely involves replenishing electrolytes, correcting hypotension with intravenous fluids and vasopressors if necessary, monitoring for dysrhythmias, and treating seizures.
- Ethanol, although not well studied as an antidote, is relatively familiar, readily available, and can be administered safely. The efficacies of other experimental antidotes are unknown.

116 PHOSPHORUS

Michael C. Beuhler

Phosphorus (P)

Atomic number = 15

Atomic weight = 30.97 Da

Normal concentration

Serum = 3–4.5 mg/dL (1–1.4 mmol/L)

HISTORY AND EPIDEMIOLOGY

Phosphorus is a nonmetallic element not naturally found in its elemental form; it was isolated from distilled urine by Hennig Brandt in 1669. White phosphorus has been used in munitions (mortar rounds, grenades, artillery shells, bombs) since World War I for its antipersonnel effect as well as its warning, incendiary, and smoke producing properties. It is also used in fireworks made in countries other than the United States and China and for selected chemical synthetic processes (including some pesticides). White phosphorus was used extensively in the past as a rodenticide but is no longer employed for this purpose in the United States. Because of the potential use of red phosphorus for illicit drug manufacture (methamphetamine), its sale is monitored by the US Drug Enforcement Administration, which limits its availability in the United States. Before modern regulation, it was used in scientifically unsubstantiated remedies primarily because its phosphorescent and reactive qualities suggested potency. Its occasional use for homicides was limited by its glowing, smoking qualities. It remains a common method of suicide in some countries.

At the beginning of the 20th century, phosphorus was used in millions of “strike anywhere” matches (lucifers). However, safety concerns with the matches and illnesses in the workers producing the matches prompted a shift from using the more dangerous white phosphorus in the match heads to substituting the safer red phosphorus in the strikers. Workers chronically exposed to white phosphorus developed “phossy jaw,” an illness characterized by disfiguring osteonecrosis of the mandible along with multiple draining abscesses.

CHEMISTRY

Phosphorus, atomic number 15, is in a group of 15 nonmetallic elements sharing chemical properties with nitrogen (above) and arsenic (below) in the periodic table. Elemental phosphorus can exist in several different allotropes (polymorphs); the two common forms considered here are red phosphorus and the highly reactive white phosphorus. The relatively nontoxic and nonreactive black form will not be considered further.

White phosphorus is a waxy whitish to yellow solid with a melting point of 111.4°F (44.1°C). Often there is a small amount of red phosphorus in samples of white phosphorus, resulting in discoloration and explaining the term, “yellow” phosphorus. The word “phosphorus” means light-bearer, which originates from its property of glowing when exposed to air, due to the formation of reactive luminescent phosphorus oxides on its surface. Phosphorus is insoluble in water and often stored under it, but soluble in carbon disulfide and other organic solvents. White phosphorus is very reactive, igniting spontaneously in air at approximately 93°F (34°C), oxidizing to form phosphorus pentoxide (P_4O_{10}), which usually appears as a white fume having a garliclike smell. Phosphorus pentoxide is hygroscopic and reacts with water to form phosphoric acid (H_3PO_4) and reacts with organic molecules in dehydrating reactions.

Red phosphorus is a red powdery compound of limited toxicologic significance. It is not luminescent, it does not combust in air, and its toxicity is orders of magnitude less than that of white phosphorus.

TOXICOKINETICS

White phosphorus is well absorbed from the intestinal tract, and coingestion with fats, alcohol, and liquids increases toxicity, probably from increased absorption.^{6,7} White phosphorus is also well absorbed through the skin, with burns contributing to the absorption; significant morbidity and mortality occurring from large surface area burns. White

phosphorus can also be absorbed by inhalation, although this exposure route is rare with current industrial hygiene practices. After ingestion, phosphorus is found in high concentrations within 3 hours in the blood, liver, and kidneys.^{4,12}

Internally absorbed white phosphorus has significant toxicity. A dose of only about 1 mg/kg in adults is likely to cause significant morbidity, but a lethal dose of 3 mg is reported in a child.³ The mortality from white phosphorus ingestion is difficult to estimate, because the majority of reported cases occurred prior to the development of critical care. Historically, significant ingestions carried a 25% mortality rate.¹⁰

PATHOPHYSIOLOGY

The mechanism of dermal injury from white phosphorus differs significantly from that of ingested white phosphorus. Externally, white phosphorus reacts with oxygen to form phosphorus pentoxide and other phosphorus oxides. Phosphorus pentoxide readily reacts with water in an exothermic reaction, producing corrosive phosphoric acid.¹³ Additionally, phosphorus pentoxide reacts with (dehydrates) some organic molecules. These three mechanisms (exothermic, acid-producing, and dehydrating reactions) all contribute to the tissue injury observed, although the most damaging mechanism is the thermal injury from the heat of the reaction, as evidenced by the relatively short distance of tissue penetration by the acid and the relatively large amount of available water.^{5,20} The evidence for describing white phosphorus as a cytoplasmic toxin is mostly derived from electron microscopy, which demonstrates an initial cytoplasmic injury of the rough endoplasmic reticulum rather than initial nuclear or mitochondrial changes; but white phosphorus may also have an effect on mitochondrial energetics.¹¹

Red phosphorus has limited direct toxicological significance. It can cause gastrointestinal (GI) irritation when ingested in significant amounts, but it is orders of magnitude less toxic than white phosphorus.

A resurgence of toxicity and human injury indirectly related to red phosphorus has resulted from the increase in North American domestic methamphetamine production. Red phosphorus is used in conjunction with elemental iodine to produce hydroiodic acid, the ultimate reducing agent required to convert ephedrine to methamphetamine. In this situation, red phosphorus contributes to human injury by causing fire due to its unintentional conversion to highly flammable white phosphorus. Additional pathology occurs because during heating, the reaction products of iodine and red phosphorus often generate phosphine (PH_3), a pulmonary irritant and metabolic inhibitor gas (Chap. 124). Phosphine is only produced in significant amounts during an active methamphetamine “cook” using the red phosphorus method. This gas most likely contributes to some of the pulmonary effects occurring with chronic exposures in methamphetamine laboratories, as well as several of the deaths resulting from performing the synthesis in an area with limited ventilation in order to hide the characteristic odors.²¹ Unless specifically stated, all further references to phosphorus in this chapter refer to white phosphorus.

CLINICAL MANIFESTATIONS

General

The clinical manifestations of oral phosphorus poisoning are classically described in three stages. The initial effects may be delayed for a few hours, and the degree of delay depends on the dose. During the first phase, patients experience vomiting, hematemesis, and abdominal pain, with hypotension and death occurring within 24 hours after large ingestions.⁷ During the second stage, there is transient resolution of the toxic effects. During the third stage, the patient develops hepatic injury with coagulopathy and jaundice and acute kidney injury with oliguria and uremia. Mental status changes and seizures (independent of electrolyte changes) are also reported. However, clinical experience demonstrates that three distinct phases are the exception rather than the rule, with significant overlap or absence of the “quiescent” second stage and death potentially occurring within hours of ingestion.^{6,15} In the first 6 hours postexposure, poor prognostic signs include altered sensorium, cyanosis, hypotension, metabolic acidosis, elevated prothrombin time, and hypoglycemia.⁶ Survival to 3 days serves as a good prognostic sign. However, deaths occur later in the clinical course.⁷ Recovery usually occurs over 1 to 2 weeks.

Gastrointestinal

Initial symptoms after ingestion of phosphorus include nausea, vomiting, and abdominal pain. Both diarrhea and constipation are reported but are much less common. The breath and vomitus are sometimes described as having a garlic or musty sweet odor. The vomitus and diarrhea are sometimes luminescent and smoking, but this specific finding occurs infrequently. The smoking material is caused by the combustion of phosphorus upon its reexposure to air after being eliminated from the GI tract. Phosphorus causes an inflammatory injury to the GI tract characterized by local hemorrhage and hematemesis, but generally perforation does not occur. Massive GI bleeding may occur later in the clinical course, particularly when hepatic failure and coagulopathy are present.¹⁰

Renal/Electrolytes

In a rat model of dermal burns from phosphorus, an initial diuresis occurs followed by acute kidney injury manifested by hyperkalemia, hyponatremia, and hyperphosphatemia.¹ Renal cell swelling and necrosis with vacuolar degeneration of proximal convoluted tubules was also observed.¹ Poisoned patients demonstrated an increase in urinary white and red blood cells with casts and proteinuria.³ In humans, acute kidney injury from phosphorus is most likely acute tubular necrosis resulting from hypotension, salt and water depletion, and a direct toxic effect.⁷

Significant electrolyte disturbances may result from both ingestion and dermal absorption of phosphorus. Hypocalcemia is common, but hypercalcemia is also occasionally reported.¹³ Hyperphosphatemia may accompany the hypocalcemia but is not universal and can occur at any time in the clinical course.³ The hyperphosphatemia is partially due to the conversion of absorbed phosphorus to phosphate. In an animal model, those that died had increased concentrations of phosphorus, decreased concentrations of calcium, and hyperkalemia as early as one hour postexposure.² Hyperkalemia is occasionally reported in humans and may be secondary to tissue injury and acute kidney injury.¹ The electrolyte disturbances are likely a leading cause of early mortality from phosphorus.

Cardiovascular

Death within 24 hours of the ingestion is likely the result of cardiovascular collapse. One series of 41 patients who attempted suicide demonstrated a variety of initial electrocardiographic (ECG) abnormalities. T wave changes predominated in 24 patients, and there were also two cases of ventricular fibrillation. An increasing number of ECG abnormalities occurred in patients with larger ingestions, although the electrolyte abnormalities were not described in many patients.⁷ An animal model of phosphorus exposure demonstrated prolonged QT interval and ST segment changes along with electrolyte abnormalities, suggesting that many of the ECG changes might be due to electrolyte abnormalities.² A small study of phosphorus exposure in rats observed a decrease in amino acid uptake in myocytes suggesting a direct toxic effect. Human autopsies of several poisoned patients demonstrated fatty degeneration of the myocardium and vacuolated cytoplasm many hours postingestion.¹⁹

Hepatic

Phosphorus is a potent hepatotoxin. Increase in prothrombin time, hyperbilirubinemia, and hypoglycemia usually occur within 3 days, with earlier signs of hepatic failure such as jaundice and coagulopathy indicative of a poor prognosis.^{7,14} The increase in hepatic aminotransferases occurs over several days, usually peaking at or below 1000 IU/L and almost invariably less than 3000 IU/L.¹⁰ Other biochemical effects demonstrated by experimental phosphorus toxicity include an increase in glucose-6-phosphate activity and impairment of triglyceride metabolism and protein synthesis. When death occurs after several days (as opposed to within 24 hours), hepatic injury is usually implicated. If survival occurs, the hepatic damage usually resolves over several months, although persistent periportal fibrosis is reported.¹⁴

With absorption of sufficient quantities, phosphorus causes a dose-related zone 1 or periportal hepatic injury, in contrast to the centrilobular pattern (zone 3) that occurs with other hepatotoxins, such as acetaminophen and carbon tetrachloride ([Chap. 23](#)). Fatty degenerative changes and fatty infiltrates are also observed within 6 hours of ingestion.⁶ Other histological changes include acute necrosis with large vacuoles and inflammatory changes. Electron microscopy in a rat model demonstrated an increase in the rough endoplasmic reticulum and an increase in the cytoplasmic fat without initial mitochondrial or nuclear injury.¹¹ Although the early pathological effects appear to be predominantly cytoplasmic, the formation of nuclear vacuoles can occur.¹⁴

Nervous System

Central nervous system effects include headache, altered mental status, coma, and rarely seizures. The altered mental status is probably due partially to the presence of other organ dysfunction and shock; one example of the former is the encephalopathy secondary to hepatic injury. Patients with initial alterations in mental status or coma have an increased mortality rate independent of the presence of any electrolyte abnormalities.¹⁵

Dermal/Mucous Membranes

Dermal phosphorus exposure causes extensive burns, and this occurs most frequently in the military setting. The burns are described as emitting a garlic odor and displaying a yellow color that fluoresces under ultraviolet light. Necrosis of the wounds is common when wound decontamination is incomplete. Depending on the release conditions, white phosphorus can be a solid or liquid. Liquid white phosphorus splatters and can penetrate clothing; burning clothing commonly exacerbates the burn area.^{13,16} Dermal penetration may be partially due to its lipophilicity and a compromised dermal barrier caused by the burn injury. The smoke produced by burning white phosphorus contains phosphorus pentoxide and is

irritating to the conjunctiva and mucosa of the oropharynx and lungs.

Following a large burn, systemic illness manifested by electrolyte, cardiovascular, and hepatic abnormalities may result from absorbed phosphorus.^{1,2} A 12% to 15% body surface area burn in a rat was lethal 50% of the time; human morbidity from large skin burns is similarly high. Rats with dermal burns from phosphorus subsequently developed kidney and liver injury. Healing time from phosphorus burns is prolonged when compared with thermal burns.⁷

DIAGNOSTIC TESTING

Serum elemental phosphorus concentrations are not clinically available, and a serum phosphate concentration does not reflect the serum elemental phosphorus concentration. The diagnosis of phosphorus poisoning must rely on the history and physical examination. However, for optimal supportive care of the patient, many laboratory factors must be monitored such as ECG, electrolytes, serum pH, hepatic function, glucose, renal function, and coagulation parameters.

MANAGEMENT

Protection of Health Care Workers

Caution should be exercised in decontamination and subsequent storage of contaminated clothing. Vomitus and diarrhea must be considered potentially hazardous due to fire risk and should be carefully handled. Any phosphorus fragments removed from the patient as well as all potentially contaminated clothing items should be kept under water. Fires and explosions are reported during GI decontamination efforts, and the smoke from burning white phosphorus is irritating to the eyes and pulmonary system.¹⁷

General

General supportive care is the mainstay of treatment. Cardiac monitoring; frequent analysis of calcium, phosphate, and potassium concentrations, and serial ECGs are essential for patients with a history of significant ingestion or overt toxicity as dysrhythmias may occur rapidly.⁷ Electrolyte disturbances such as hyperkalemia, hypocalcemia, and hypercalcemia should be corrected. With significant exposure to phosphorus, hepatic injury will occur, and thus directed supportive care should be provided such as fresh-frozen plasma and vitamin K, when indicated. Adequate serum glucose concentrations are required to provide reducing equivalents through glycolysis and the glucose-6-phosphate dehydrogenase (G6PD) pathways, especially when there is evolving hepatic injury. Increased glucose concentrations may also theoretically offer protection by competing with phosphorus reuptake in the kidney, but the contribution to human morbidity is unclear. Corticosteroids have not been shown to improve outcome following ingestions of white phosphorus.¹⁴ Direct contact of phosphorus with the eye can result in serious ophthalmic injury. Immediate copious ophthalmic decontamination with water rather than with copper sulfate is recommended (see Dermal Exposure).¹⁸ A careful examination should be conducted by an ophthalmologist whenever possible.

Dermal Exposure

Initial treatment is to halt continuing injury by extinguishing combustion of the phosphorus. This is performed by submerging the affected area in cool water or, more practically, covering any areas with clean materials soaked in water or a 0.9% sodium chloride solution to limit the white phosphorus contact with atmospheric oxygen. Decontamination is undertaken by removing clothing and using large amounts of cool water to remove any phosphorus fragments. In the past, sodium bicarbonate decontamination solution was recommended, but because the tissue injury is not due to the production of acid and because no clinical benefit was demonstrated, there is no current role for specific neutralization fluids.^{5,20} Water dilutes any phosphoric acid present and reacts with the phosphorus pentoxide to limit the damaging dehydrating reactions.

Careful débridement is the next critical step as wounds that have not undergone adequate decontamination heal poorly, requiring additional débridement. Smoking pieces of phosphorus are not necessarily hot enough to cause thermal burns, but the oxidation process must be arrested. Fragments of phosphorus from the wound should be placed under water to prevent a fire hazard. Particles of phosphorus can be visualized by using a Woods lamp as the chemical burns have a yellowish fluorescence. One author recommends turning off the lights to look for the glow of the phosphorescent particles; presumably this will work only if there has not been any copper or silver metal wash solution used, but others have questioned if the amount of glow will be enough to locate fragments under real world conditions (see following paragraphs).⁸ Because of the increased solubility of phosphorus in hydrophobic solvents, it is important not to use ointments until the wound is completely decontaminated.

A copper (II) sulfate solution was previously recommended for “decontamination.” Copper sulfate reacts with phosphorus to produce copper phosphide, a dark compound that is much more easily visualized in the tissues. This dark material coats the particle, but the entire particle is not converted to copper phosphide. Additionally, this coating decreases

the reaction of phosphorus with oxygen for a limited time. The use of high concentrations of copper sulfate solutions on exposed human flesh is no longer recommended because of potential systemic toxicity such as hemolysis caused by the copper (Chap. 95).¹⁸ This is especially concerning in patients at increased risk for oxidant injury, such as those with G6PD deficiency. The solutions of copper sulfate historically used ranged from 2% to 5% and were applied for several hours to the wounds, resulting in substantial amounts of copper absorption and morbidity.

However, copper sulfate solutions still may have a role in the complete approach to the treatment of phosphorus wounds. A dilute copper sulfate solution (0.5%–1.0%) applied once to the wound and then rinsed off with water may not result in the morbidity that occurs with the more concentrated rinses and may provide temporary neutralization of the outer surface of the phosphorus. This approach may assist in identification of the small pieces of phosphorus that are difficult or impossible to visualize by darkening the fragments, especially in those with less experience débriding these wounds. Wounds that are not treated with a copper solution may be at greater risk of requiring repeat débridement because of the persistence of small phosphorus particles missed during the initial decontamination efforts. Animal models have suggested improved healing from the initial treatment with a dilute copper solution, but a relatively large human case series did not find a difference in those who were treated with copper sulfate compared with those who were not.⁵ The copper phosphide-coated particles must be removed as they still react slowly and can cause toxicity. It is important to remember that the dilute copper sulfate solution is not a decontamination therapy but a temporizing treatment that allows for better visualization for physical débridement, and this solution must be rinsed away immediately after application.⁸ The use of pads soaked in copper sulfate is not recommended.

Silver nitrate has been suggested as a potential solution to replace the use of copper sulfate. It forms an insoluble, minimally reactive silver phosphide. Its use and preparation is similar to that described above and as such silver nitrate (1%–2% solution) should be considered as a temporary neutralization tool and not a decontamination therapy. It does not have the detrimental physiologic effects that internalized copper ions cause. However, there is very limited experience with this approach and no detailed human data. Silver forms an insoluble precipitate with chloride and cannot be combined with 0.9% sodium chloride solutions; therefore, the amount of soluble silver ion that reaches the imbedded phosphorus may be more limited than with copper because of the presence of relatively large amounts of chloride ion in living tissues.²²

A reasonable approach is to begin by decontaminating the wound using a Woods lamp and or a darkened room looking for phosphorescence. Only then applying a transient dilute copper sulfate or silver nitrate wash as described above is indicated to improve visualization and possibly neutralize very small phosphorus particles. After decontamination, good wound care and burn management is required, because these burns (like other chemical burns) can require an extended period of time to heal. As discussed, incomplete decontamination is a common reason for delayed wound healing. For significant burns, the patient should be admitted to a burn intensive care unit for close monitoring of cardiovascular, renal, and electrolyte status for several days at the minimum. Because of the potential instability of these patients, it is important to weigh the risk-to-benefit ratio of transfer to a specialized center. The experience of the receiving center with phosphorus burns in addition to the acuity and severity of the injury are important factors in making this decision.

Gastrointestinal Exposure

There is no evidence that GI decontamination or antidotal therapy following phosphorus ingestion is efficacious. In the past, several different lavage fluids were recommended, ranging from the mostly benign (sodium bicarbonate) to the potentially dangerous (potassium permanganate). Milk might also be potentially harmful because of its lipophilic components. Some authors postulate better outcome with earlier GI decontamination, but no reliable studies are available.¹⁴ Activated charcoal may bind to white phosphorus and could be considered, although there are no human data to support its use. However, despite the lack of data of efficacy, given the poor outcome of patients with large ingestions of phosphorus, decontamination efforts should be strongly considered. If lavage is considered, a nasogastric tube would not be expected to remove substantial quantities due to the insoluble, solid nature of phosphorus. The tissue injury caused by phosphorus is not expected to cause early esophageal perforation, and the use of an orogastric (OG) tube would therefore be best. Caution to protect caregivers should be exercised with any lavaged material. Due to the risk of fire and explosion, one author recommends keeping the free end of the OG tube under water while inserting and instilling small amounts of water (not air) to check for proper placement.¹⁷

It appears that the hepatic injury is much more likely with ingested phosphorus exposure than following dermal exposure. N-acetylcysteine (NAC) is suggested as a potential adjunct in the treatment of phosphorus toxicity. Although NAC was used in a limited human series, the numbers were small.¹⁰ The use of superoxide dismutase in an animal model suggested benefit but did not limit morbidity, and a separate animal model suggested benefit from glutathione; therefore, limiting oxidant injury may play a role in treatment.⁹ There is no theoretical harm in using NAC for phosphorus toxicity, and so it should be added to the treatment regimen. Methionine was used many years ago in the treatment of a few patients, but the number of treated patients was too few to draw any conclusions.⁶ When liver transplantation was performed for phosphorus induced hepatic failure outcomes have been suboptimal, likely due to toxicity occurring in the central nervous and cardiovascular systems.

SUMMARY

- White phosphorus was most commonly used in warfare, causing morbidity through dermal burns.
- These burns require large amounts of water irrigation and adequate débridement while protecting health care workers.
- Following ingestion, typically in suicide attempts, morbidity remains quite high, and treatment options are limited to unproven decontamination therapies.
- Signs and symptoms of white phosphorus toxicity include vomiting, abdominal pain, confusion, dysrhythmias, hepatic injury, and acute kidney injury.
- As early mortality is believed to be due to electrolyte abnormalities and cardiac dysrhythmias, vigilant critical care is the mainstay of therapy.
- NAC may be used, but it has not been shown to alter human outcomes.

117 STRYCHNINE

Yiu-Cheung Chan

HISTORY AND EPIDEMIOLOGY

Strychnine alkaloid occurs naturally in *Strychnos nux-vomica*, a tree native to tropical Asia and North Australia, and in *Strychnos ignatii* and *Strychnos tiente*, trees native to South Asia. The alkaloid was first isolated in 1818 by Pelletier and Caventou.^{5,15} It is an odorless and colorless crystalline powder that has a bitter taste when dissolved in water. Besides strychnine, the dried seeds of *S. nux-vomica* contain brucine, a structurally similar, although less potent, alkaloid.⁸⁸ Strychnine is available from commercial sources in its salt form, usually as nitrate, sulfate, or phosphate.

Strychnine was first introduced as a rodenticide in 1540, and in subsequent centuries was used medically as a cardiac, respiratory, and digestive stimulant,⁴⁵ as an analeptic,⁹² and as an antidote to barbiturate⁹¹ and opioid overdoses.⁵⁹ Nonketotic hyperglycemia,^{9,36,80} sleep apnea,⁷⁶ and snake bites¹⁵ were also once considered indications for strychnine use. In 1982, at least 172 commercial products were found to contain strychnine, including 77 rodenticides, 25 veterinary products, and 41 products made for human use.⁸³ However, the use of strychnine was substantially decreased; some countries such as the European Union banned its use as a rodenticide in 2006, and most of its prior medicinal indications are no longer utilized. Currently, strychnine is used as a rodenticide (for moles, gophers, and pigeons) and a research tool for the study of glycine receptors. Most commercially available strychnine-containing products contain about 0.25% to 0.5% strychnine by weight.⁸³

Between 1926 and 1928, strychnine killed more than three Americans every week.^{5,27} In 1932, it was the most common cause of lethal poisoning in children,^{5,83,98} and one-third of the unintentional poison-related deaths in children younger than 5 years were attributed to strychnine.⁶⁰ Currently, strychnine poisoning is rare and continues to decrease in the United States, although deaths are still reported. The Toxic Exposure Surveillance System (TESS) and National Poison Data System (NPDS) data of the American Association of Poison Control Centers (AAPCC) reported 1414 strychnine exposures during the past 10 years (2002–2011), with only eight deaths (Chap. 136).

Strychnine poisoning has resulted from deliberate exposure with suicidal and homicidal intent,^{27,50} as well as from unintentional poisoning by a Chinese herbal medicine (Maqianzi)¹⁶ and a Cambodian traditional remedy (slang nut).^{47,49,51,86} Maqianzi is used to treat limb paralysis, severe rheumatism, and inflammatory disease, whereas slang nut is used to treat gastrointestinal illness. The bitter taste of strychnine allows it to be used to adulterate heroin⁴³ and cocaine.^{13,22,64} There are also reports of strychnine poisoning from adulterated amphetamines,²² 3,4-methylenedioxymethamphetamine (MDMA),²⁵ Spanish fly,¹² and from the ingestion of gopher bait.⁵²

TOXICOKINETICS

Standard references list the lethal dose of strychnine as approximately 50 to 100 mg^{18,33,34,70,94} (1–2 mg/kg). However, mortality resulting from doses as low as 5 to 10 mg and, alternatively, survival following ingestions of 1 to 15 g of strychnine are reported.^{6,18,82,97} Some of this variation may be attributed to the route of administration, with parenteral administration being more toxic than oral, and the limitations of self-reported exposure quantities.

Strychnine is rapidly absorbed from the gastrointestinal tract and mucous membranes. There is a case of reported

poisoning as a result of dermal absorption of strychnine from an alkaline solution, in which strychnine exists in the nonionized, alkaloid form.³⁵ Protein binding is minimal, and strychnine is rapidly distributed to peripheral tissues⁹³ with a large volume of distribution (13 L/kg).⁴⁰ Based on postmortem findings, the highest concentrations of strychnine are found in the liver,^{57,70,78} bile,⁷⁰ blood,⁷⁰ and gastric contents.^{70,78} Relatively less strychnine is identified in kidney, urine, and brain.⁷⁸

Strychnine is metabolized by hepatic cytochrome P450 isozymes, mainly CYP3A4,^{1,53,61} producing strychnine-N-oxide as the major metabolite,¹ the toxicity of which is about one-tenth of that of the original alkaloid.⁵⁵ This metabolism is increased by P450 induction.^{44,48} Several urinary metabolites are identified,⁶⁵ and 1% to 30% of strychnine is excreted unchanged in urine,^{10,39,69} in decreasing proportions when larger amounts are ingested.^{81,93} Strychnine follows first-order kinetics with an elimination half-life of 10 to 16 hours.^{26,69,95}

PATHOPHYSIOLOGY

Glycine, one of the major inhibitory neurotransmitters in the spinal cord, opens a ligand-gated chloride (Cl^-) channel, thus allowing the inward flow of Cl^- (Fig. 14–12).²⁰ As Cl^- moves inward, the cell becomes hyperpolarized, reducing neuronal excitability. Strychnine competitively inhibits the binding of glycine to the α -subunit of the glycinergic chloride channel.^{13,19,96,98} Although strychnine affects all parts of the central nervous system in which glycine receptors are found, the most significant effect is in the spinal cord. With loss of the glycine inhibition at the motor neurons in the ventral horn, there is a loss of inhibitory influence on the normally suppressed reflex arc. The result is increased impulse transmission to the muscles, producing generalized muscular contraction. Rabbits pretreated with glycine had a 40% increase in the strychnine “seizure” threshold, illustrating the competitive nature of strychnine and glycine activity on the glycinergic chloride channel.^{17,77} Tetanus toxin (tetanospasmin) causes an identical clinical syndrome of muscular contractions but does so by preventing the release of presynaptic glycine and does not function as a competitive antagonist. In dogs, strychnine also has positive chronotropic and inotropic effects on the heart,⁸⁴ but this effect is unlikely to exert a major effect in human poisoning.

CLINICAL MANIFESTATIONS

Oral strychnine poisoning is characterized by a rapid onset of signs and symptoms beginning within 15 to 60 minutes of ingestion³² and, although less well documented, effects begin even sooner after parenteral or nasal administration. Delayed onset of clinical effects are rarely reported.^{23,34} The typical findings of poisoning are involuntary, generalized muscular contractions resulting in neck, back, and limb pain. The contractions are easily triggered by trivial stimuli (such as turning on a light), and each episode usually lasts for 30 seconds to 2 minutes.⁸³ These episodes may recur for as long as 12 to 24 hours. Differences in the strength of various opposing muscle groups result in the classic signs of opisthotonus, facial trismus, and risus sardonicus, with flexion of the upper limbs and extension of lower limbs predominating. Hyperreflexia, clonus, and nystagmus^{11,62} are also evident on examination. Because strychnine affects glycine inhibition mainly in the spinal cord, the patient typically remains fully alert until metabolic complications arise. The combination of convulsive motor activity involving both sides of the body in the conscious patient has often resulted in imprecise descriptions such as “conscious seizure” or “spinal seizure.” Hemodynamically, both hypotension,^{24,26,64} or hypertension^{13,29,63} in the presence of bradycardia^{14,24,26,64} or tachycardia^{13,14} are reported. Hyperthermia, presumably from increased muscular activity, is typical, and temperatures as high as 109.4°F (43°C) are reported.¹³ Other nonspecific signs and symptoms include dizziness, vomiting, and chest and abdominal pain.⁶²

Early in the course of strychnine poisoning, mortality is mainly due to hypoventilation and hypoxia secondary to muscular contractions.²⁹ Life-threatening complications include rhabdomyolysis with subsequent myoglobinuria and acute kidney injury,¹⁴ hypoxia or hyperthermia-induced multiorgan failure, aspiration pneumonitis,⁸⁵ anoxic brain injury, and pancreatitis.⁴² Rarely, local neuromuscular sequelae such as weakness, myalgia, and anterior tibial compartment syndrome are reported.¹³ As might be expected, the prognosis is related to the duration and extent of the episodes of muscle contractions.³¹

DIFFERENTIAL DIAGNOSIS

The diagnosis of strychnine poisoning is mainly established on clinical grounds, based on exposure history and compatible clinical manifestations, but can be confirmed by detection of strychnine in biological specimens. Several diagnoses need to be considered, the most important of which is tetanus because it produces similar muscular hyperactivity. In a patient with tetanus, however, the onset of symptoms is more gradual and the duration much longer than in the case of strychnine

poisoning. Frequently, the diagnosis of tetanus is suggested by a history of recent injury, or the finding of an obvious wound. In general, patients with tetanus have either undocumented or incomplete tetanus immunization.

Strychnine poisoning can be differentiated from generalized seizures by the presence of a normal sensorium during the period of diffuse convulsions. That is, most patients with bilateral convulsions are having generalized seizures, which by definition involve the reticular activating system, producing unconsciousness. It is conceivable, although extraordinarily rare, to have bilateral focal seizures producing apparent “generalized” convulsions. In this case, because the reticular activating system may not be involved, the mental status of the patient may be preserved. The presence of consciousness in a patient with a generalized convulsion may be sufficient to establish the diagnosis of strychnine poisoning or tetanus at least in the early phase of the clinical course. As time progresses and management is delayed this finding may be obscured by metabolically induced alterations in sensorium.¹⁷ When there is an alteration in the level of consciousness, an electroencephalogram may be helpful, to document the presence or absence of a seizure focus. A computed tomography scan of the head can help to exclude structural brain lesions, and a lumbar puncture is helpful to exclude meningitis or encephalitis. Hypocalcemia, hyperventilation, and myoclonus secondary to kidney or liver failure are evaluated by appropriate routine laboratory testing. Although a drug induced dystonic reaction should be considered when there is a relevant history, dystonic reactions are usually static, whereas strychnine poisoning results in dynamic muscular activity. Serotonin toxicity, malignant hyperthermia, neuroleptic malignant syndrome, and stimulant associated toxicity should be considered if the medical history is supportive.

DIAGNOSTIC TESTING

Respiratory and metabolic acidosis both occur commonly in strychnine-poisoned patients. Metabolic acidosis is associated with elevated serum lactate concentrations,¹³ whereas respiratory acidosis secondary to hypoventilation results from diaphragmatic and respiratory muscle failure. Survival of patients with serum pHs in the range of 6.5 to 6.6 is well documented.^{13,29,30,32,54,95} The lowest pH and highest lactate concentration reported in a patient who subsequently had full recovery was 6.5 and 32 $\mu\text{mol/L}$,^{13,95} respectively. Thus, profound acidemia in strychnine poisoning is not necessarily associated with a poor prognosis.^{7,8,13,73} In contrast to the metabolic acidosis with elevated lactate concentration that occurs in shock, the elevated lactate concentration of strychnine poisoning results from overactivity of the muscle instead of undersupply or underutilization of oxygen and nutrients.

Besides acidemia, other laboratory abnormalities expected from prolonged muscular activity include hyperkalemia and those associated with rhabdomyolysis and acute kidney injury.¹³ There is also stress-induced leukocytosis,^{13,42} elevated liver enzyme concentrations,^{42,62,90} hypocalcemia,^{13,40} hypernatremia,³² and hypokalemia.^{28,62,85} The electrocardiogram is expected to remain normal or reflect changes consistent with the above electrolyte disturbances.⁴⁰ Chest radiography may show evidence of aspiration pneumonitis or acute respiratory distress syndrome.

Strychnine can be detected by a variety of methods such as thin-layer chromatography,^{66,89} high-performance liquid chromatography,² ultraviolet spectrometry,⁶⁶ a simple colorimetric reaction,⁶⁶ gas chromatography–mass spectrometry,^{14,57,69,78} gas chromatography flame ionization detector,⁹⁴ and capillary electrophoresis.⁹⁹ With the exception of the bedside colorimetric reaction, none of these tests are routinely available in a time frame useful to assist in clinical decisions. Strychnine is also detectable in amounts as low as 0.01 mg/L in tissue,^{2,21,58,72} and strychnine resists postmortem putrefaction. Additionally, even when available, quantitative concentrations do not correlate with clinical toxicity. Reported blood strychnine concentrations in fatal poisoning ranged from 0.5 to 61 mg/L.⁹⁴ Conversely, the highest initial blood concentration associated with survival was 4.73 mg/L from blood drawn 1.5 hours postingestion⁹⁵; a concentration as low as 0.06 mg/L was found in a patient who solely had muscular irritability.²⁶

MANAGEMENT

In patients with strychnine poisoning, inducing vomiting is absolutely contraindicated because of the risk of aspiration and loss of airway control following rapid onset of muscle contractions. Gastric lavage should be considered on an individual basis after evaluating potential benefits and risks.³ When gastric lavage is thought to be indicated, it may be important to protect and secure the airway with an endotracheal tube before attempting lavage. Activated charcoal (AC) binds strychnine effectively at a ratio of approximately 1:1; 1 g of AC will bind 950 mg of strychnine.^{4,88} In animal models, pretreatment⁶⁷ and posttreatment⁷¹ with AC increase the median lethal dose in 50% of test subjects (LD_{50}) for strychnine. Clinical evidence of the effectiveness of AC for strychnine ingestion was first demonstrated in 1831, when Professor Touery survived the ingestion of a lethal dose of strychnine by using AC in a demonstration before the French Academy of Medicine.

Currently, there is no evidence to recommend the use of multiple-dose AC or whole-bowel irrigation for strychnine poisoning. Although forced diuresis was once suggested as an effective means of enhancing the elimination of strychnine,⁸⁸

subsequent data failed to demonstrate an increase in clearance⁸¹ and it is therefore no longer recommended. Peritoneal dialysis, hemodialysis, and hemoperfusion have not been extensively studied. However, because strychnine is rapidly distributed to the tissues⁹³ with a large volume of distribution (13 L/kg), extracorporeal drug elimination procedures are unlikely to be useful and therefore not justified given their risks.

Supportive treatment remains the most important aspect of management in the majority of cases. The focus of care is to stop the muscular hyperactivity as soon as possible to prevent the metabolic and respiratory complications. At all times, unnecessary stimuli and manipulation of the patient should be avoided, as these activities trigger muscle contractions. Benzodiazepines remain the first line treatment for strychnine induced muscular hyperactivity.^{83,95} Although much of the evidence concerning the efficacy of benzodiazepines is based on clinical experience with diazepam,^{38,46,64} any of the other commonly used benzodiazepines (midazolam or lorazepam) would likely have similar effects. The initial dose of the benzodiazepine chosen should be the standard dose used for other indications, although doses of more than 1 mg/kg diazepam or its equivalent may be needed.^{41,56} In case of failed intravenous access, lorazepam or midazolam can be given intramuscularly or intraosseously. Dosing should be repeated until the patient demonstrates muscle relaxation and the contractions cease. In addition to benzodiazepines, barbiturates and propofol are also effective, although considered secondary therapies, in stopping the strychnine-induced hyperactivity.^{37,51,74,87} Benzodiazepines and barbiturates both work through agonism of γ -aminobutyric acid (GABA) receptor chloride complexes to increase the inhibitory neurotransmission to the spinal cord from the brain, and thus raise the reflex arc threshold.⁷⁹ If these measures fail to control the muscular hyperactivity, a nondepolarizing neuromuscular blocker (NMB) should be administered. Only nondepolarizing NMBs should be used, as succinylcholine itself, a depolarizing NMB, induces muscle contractions.^{13,26,51,64,81} It is important to remember that strychnine has no direct effects on consciousness, so that sedation must always accompany neuromuscular blockade. Generally, therapy is continued for about 24 hours, at which time the benzodiazepines and or NMBs can be tapered as tolerated.

The most important therapy for the metabolic complications of strychnine poisoning is to expeditiously stop the production of metabolic byproducts by terminating the muscular hyperactivity. Hyperthermia should be treated rapidly by active cooling with ice water immersion, cooling blanket, or mist and fan, depending on the magnitude of temperature elevation. Means to prevent rhabdomyolysis induced acute kidney injury include adequate fluid administration to ensure good urine output (> 1 mL/kg/h), the potential use of urinary alkalization with sodium bicarbonate,⁷⁵ and temporary renal replacement therapy, if acute kidney failure occurs. Metabolic acidemia rapidly resolves when muscular activity is controlled.^{13,68}

Effective management in the first few hours of strychnine poisoning is crucial for survival. If the patient can be supported adequately for the first 6 hours, this may be considered a good prognostic sign.^{13,34} All significantly poisoned patients should be managed in an intensive care unit with the help of a regional poison center or a medical toxicologist. For patients unintentionally exposed to strychnine who remain asymptomatic, an observation period of 12 hours is sufficient to exclude significant risk.

SUMMARY

- Strychnine is a lethal poison that is no longer frequently encountered, except in areas where it is used as a rodenticide.
- A “conscious seizure” is the characteristic presentation of strychnine toxicity, and is rapidly followed by life threatening metabolic and respiratory consequences.
- The mainstay of treatment is supportive care with the goal of rapidly terminating muscular contractions, providing adequate airway management, and rapidly treating hyperthermia and or metabolic abnormalities.
- Although benzodiazepines are generally sufficient, neuromuscular paralysis with a nondepolarizing NMB may be required.
- Generally, the prognosis of strychnine poisoning is good, if the patient can be adequately supported and survives the first few hours of toxicity.

L. NATURAL TOXINS AND ENVENOMATIONS

CASE STUDY 10

History A 32 year-old woman with no past medical history presented to the emergency department with a 2 day history of a painless, rapidly expanding lesion on her back. She first noticed the lesion 2 days prior but did not recall any trauma or other inciting factors. The woman denied headache, shortness of breath, chest pain, nausea, vomiting, diarrhea or dysuria, but she reported subjective fever and malaise for 2 days. She was not taking any medications, she drank alcohol socially, and she denied intravenous drug use. She worked as an accountant in New York City and traveled frequently to a vacation home in Montauk, Long Island.

Immediate Assessment and Management On presentation to the emergency department, the patient was well appearing and in no apparent distress. Vital signs were: blood pressure, 102/52 mm Hg; pulse, 92 beats/min; respiratory rate, 16 breaths/min; tympanic temperature, 98.7°F (37.1°C); and oxygen saturation, 100% on room air. A complete physical examination was entirely within normal limits, except for her skin examination. This was notable for a solitary 9 cm annular plaque on the upper back with central hemorrhagic crust overlying a 5 cm violaceous plaque surrounded by a ring of erythema (Fig. CS10–1). The lesion was only mildly tender to palpation, and there was no underlying fluctuance.

FIGURE CS10-1 The lesion on the woman's back, reproduced with her permission.

What Is the Differential Diagnosis? The only remarkable finding in this patient is the 2 day old skin lesion, associated with subjective fever and malaise. The differential diagnosis includes infectious diseases such as cellulitis or a bacterially superinfected cyst or arthropod bite, sporotrichosis, lyme disease, and anthrax (Chap. 133); drug reactions such as a fixed-drug eruption, or given the necrotic appearance of the lesion, necrosis due to warfarin or heparin therapy (Chaps. 18 and 60); and necrotic spider bites (Chap. 118).

Immediate Assessment and Management A more detailed history failed to reveal any clues. The woman specifically denied knowledge of tick or spider bites, and she neither worked, lived, nor vacationed in an area known to be inhabited by brown recluse spiders. However, she frequented an area of Long Island where ticks are endemic. An intravenous line was inserted and a complete blood count, basic metabolic panel, and liver function tests were sent; all were within normal limits. The patient was started on vancomycin to provide *Staphylococcus aureus* and methicillin-resistant *S. aureus* coverage for a presumed bacterial infection or necrotizing soft tissue infection.

Cases such as these require an immediate assessment for potential public health implications. Once a diagnosis of cutaneous anthrax is considered, the possibility of malicious exposure mandates a coordinated effort to establish a definitive diagnosis. It is important to recall that one of the cases of cutaneous anthrax that occurred following the malicious letters in New York in 2001 involved the case of a small child who was initially diagnosed with brown recluse spider envenomation. Additionally, while spider envenomation may occur outside of regions considered to be endemic as movement of spiders in suitcases, packages, or vehicles may occasionally occur, a new pattern of envenomation may represent a local infestation or the expansion of an endemic area resulting from climate changes. All of these scenarios may require public health interventions.

What Further Diagnostic and Therapeutic Interventions Are Indicated? A dermatology consult was called, and a biopsy was taken for histologic evaluation of a permanent section as well as Gram stain. An acid-fast bacillus stain was also done on the tissue for mycobacterial infection and was negative. Extensive laboratory testing was ordered to help exclude uncommon etiologies for the skin lesion. The biopsy demonstrated epidermal necrosis and dermal abscess, which are nonspecific findings. A wound Gram stain and culture failed to show white blood cells or microorganisms.

Case Resolution Serologies including a Lyme western blot, Rocky Mountain spotted fever antibodies, and *Francisella tularensis* were all negative. The vancomycin was stopped, and the woman was discharged on a 21 day course of oral doxycycline for presumed Lyme disease given the history and morphology of the lesion. The lesion began to regress on oral doxycycline. Although a final diagnosis was never established, the working diagnosis was that of either Lyme disease or a necrotic spider envenomation, and the patient's Lyme Western blot was to be repeated in 3 to 4 weeks in order to further clarify between the two leading diagnoses: Lyme or necrotic spider envenomation.

118 ARTHROPODS

In-Hei Hahn

TAXONOMY

Arthropoda means “joint-footed” in Latin and describes arthropods’ jointed bodies and legs connected to a chitinous exoskeleton.⁵ The majority of arthropods are benign to humans and environmentally beneficial. Some clinicians regard bites and stings as inconsequential and more of a nuisance than a threat to life. However, some spiders have toxic venoms that can produce dangerous, painful lesions or significant systemic effects. Important clinical syndromes are produced by bites or stings from animals in the phylum Arthropoda, specifically the classes Arachnida (spiders, scorpions, and ticks) and Insecta (bees, wasps, hornets, and ants) (Table 118–1). Infectious diseases transmitted by arthropods, such as the various encephalitides, Rocky Mountain spotted fever, human anaplasmosis, babesiosis, and Lyme disease, are not discussed in this chapter.

TABLE 118–1. Insects and Other Arthropods That Bite, Sting, or Nettle Humans	
Arthropod	Description
Honeybee (<i>Apis mellifera</i>)	Hairy, yellowish brown with black markings
Bumblebee and carpenter bee (<i>Bombus</i> spp and <i>Xylocopa</i> spp)	Hairy, larger than honeybees and colored black and yellow
Vespids (yellow jackets, hornets, paper wasps)	Short-waisted, robust, black and yellow or white combination
Schecoids (thread-waisted wasps)	Threadlike waist
Nettling caterpillars (browntail, lo, hag, and buck moths, saddleback and puss caterpillars)	Caterpillar shaped
Southern fire ant (<i>Solenopsis</i> spp)	Ant shaped
Spiders (<i>Arachnida</i>) black widow, brown recluse	Body with two regions: cephalothorax and abdomen; eight legs
Scorpions (<i>Centruroides</i>)	Eight legged, crablike, stinger at the tip of the abdomen; pedipalps (pincers) highly developed (not a true insect)
Centipedes (<i>Chilopoda</i>)	Elongated, wormlike, with many jointed segments and legs; one pair of poison fangs behind head

Arthropoda comprises the largest phylum in the animal kingdom. It includes more species than all other phyla combined (Fig. 118–1).⁵ At least 1.5 million species are identified, and half a million or more are yet to be classified. Araneism (pertaining to spiders) or arachnidism (spiders including other arachnids) results from the envenomation caused by a spider bite. “Bites” are different from “stings.” Bites are defined as creating a wound using the oral pole with the intention for either catching or envenomating prey or blood feeding,^{96,195} or for the purpose of feeding such as in arthropods that have mouthparts for chewing or sucking (plant sucking). “Stings” occur from a modified ovipositor at the aboral pole that is also able to function in egg laying as in bees and wasps. In scorpions the sting is not a modified ovipositor and the “tail” is not a tail but the metasoma section of the abdomen. Stinging behavior typically is used for defense. Most spiders are venomous, and the venom weakens the prey, enabling the spider to secure and digest their prey. However, there is one family of spiders, Uloboridae, which do not have a venom gland, a venom duct, or duct opening in the fangs. Spiders in general are

not aggressive toward humans unless they are provoked. The chelicerae (mouthparts comprised of basal section and hinged fang) of many species have fangs that are too short to penetrate human skin.

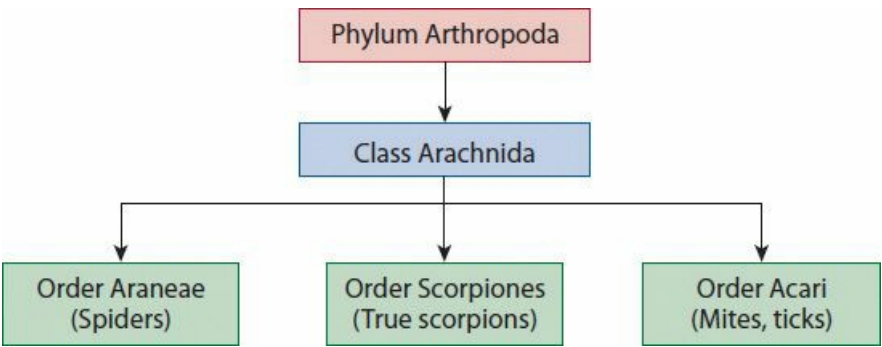

FIGURE 118-1 Taxonomy of the phylum Arthropoda.

Spiders can be divided into categories based on whether they pursue their prey as hunters or trappers. Trappers snare their prey by spinning webs, then feed on their prey and enshrine excess victims in a cocoon silk to be eaten later. The order of spiders (Araneae) differs from other members of the class (Arachnida) because of various anatomic differences best assessed by an entomologist/arachnologist. Simplistically, the arachnids have four pairs of joined legs whereas insects have three pairs. The arachnid’s body is divided into two parts (cephalothorax and unsegmented abdomen, except for some spiders in Mesothelae and also some Mygalomorph {tarantula-type} relatives that have abdominal plates) connected by a small pedicel and two, three, or four pairs (Mesothelae contain up to six pairs) of spinnerets from which silk is spun. Two pedipalps are attached anteriorly on the cephalothorax on either side of their chelicerae and are used for sensation, manipulation of food and objects, and in males are modified for sperm transfer. Spiders have eight eyes, although there are instances when they have two, four, six, or even no eyes and are quite myopic. Prey is localized by touch as they land in the spider’s web, though not all spiders produce webs and use silk to capture prey. Most spiders use venom to kill or immobilize their prey. The spiders of medical importance in the United States include the widow spiders (*Latrodectus* spp), the violin spiders (*Loxosceles* spp), and the hobo spider (*Tegenaria agrestis*). Although there is some disagreement as to the extent of the danger of hobos in the United States, hobos are not considered dangerous in Europe. In Australia, the funnel web spider (*Atrax robustus*) and *Hadronyche* species can cause serious illness and death. In South America, the Brazilian Huntsmen (*Phoneutria fera*) and *Arantia Armeadeira* (*Phoneutria nigriventer*) are threats to humans.

HISTORY AND EPIDEMIOLOGY

Since the time of Aristotle, spiders and their webs were used for medicinal purposes. Special preparations were concocted to cure a fantastic array of ailments, including earache, running of the eyes, “wounds in the joints,” warts, gout, asthma, “spasmodic complaints of females,” chronic hysteria, cough, rheumatic afflictions for the head, and stopping blood flow.²²⁷

One *Latrodectus* species has an infamous history of medical concern, hence the name mactans, which means “murderer” in Latin.¹⁸³ Hysteria regarding spider bites peaked during the 17th century in the Taranto region of Italy. The syndrome tarantism, which is characterized by lethargy, stupor, and a restless compulsion to walk or dance, was blamed on *Lycosa tarantula*, a spider that pounces on its prey like a wolf. Deaths were associated with these outbreaks. Dancing the rapid tarantella to music was the presumed remedy. The real culprit in this epidemic was *Latrodectus tredecimguttatus*.¹⁸³ Other epidemics of arachnidism occurred in Spain in 1833 and 1841.¹⁵⁶ In North America, there was an increase in spider exposures during the late 1920s; Rome reported large numbers in 1953; Yugoslavia reported a large number of cases between 1948 and 1953.^{33,156} These epidemics may be related to actual reporting biases as well as climatic variations.¹⁸³ Spider bites are more numerous in warmer months, presumably because both spiders and humans are more active during that season.

Approximately 200 species of spiders are associated with envenomations.^{192,196} Eighteen genera of North American spiders produce poisonings that require clinical intervention (Table 118–2). In one series of 600 suspected spider bites, 80% were determined to result from arthropods other than spiders, such as ticks, bugs, mites, fleas, moths, butterflies, caterpillars, flies, beetles, water bugs, and some members (ants, bees, wasps) of order Hymenoptera. Ten percent of the presumed bites actually were manifestations of other nonarthropod disorders.^{194,196}

TABLE 118–2. North American Spiders of Medical Importance

<i>Genus</i>	<i>Common Name</i>
<i>Araneus</i> spp	Orb weaver
<i>Argiope aurantia</i>	Orange argiope
<i>Bothriocyrtum</i> spp	Trap door spider
<i>Chiracanthium</i> spp	Running spider
<i>Drassodes</i> spp	Gnaphosid spider
<i>Heteropoda</i> spp	Huntsman spider
<i>Latrodectus</i> spp	Widow spider
<i>Liocranoides</i> spp	Running spider
<i>Loxosceles</i> spp	Brown, violin, or recluse spider
<i>Lycosa</i> spp	Wolf spider
<i>Misumenoides</i> spp	Crab spider
<i>Neoscona</i> spp	Orb weaver
<i>Peucetia viridans</i>	Green lynx spider
<i>Phiddipus</i> spp	Jumping spider
<i>Rheostica (Aphonopelma)</i> spp	Tarantula
<i>Steatoda grossa</i>	False black widow spider
<i>Tegenaria agrestis</i>	Hobo spider
<i>Ummidia</i> spp	Trap door spider

From 2006 to 2007, an annual average of 14,000 spider exposures and 44,000 insect exposures were reported to US poison centers.^{36,40} No more than two fatalities were reported per year. One was from the Hymenoptera category, and the other was an unknown spider exposure.³⁶ However, from 2008 to 2011 the annual average of spider and insect exposures declined to 10,900 and 39,600 exposures, respectively.^{37,38,39,41} Fatalities again were low. In 2008, one death was reported as caused by scorpion exposure; in 2009, one death was reported as caused by an “other insect bite/sting”; in 2010, two deaths were reported from bee stings and one death from an “other spider bite”^{37,38,39} (Chap. 136).

Most information on the clinical presentation of spider bites continues to be unreliable because it is based on case reports and case series. Frequently, the cases do not have any expert confirmation of the actual spider involved, which can lead to propagation of misinformation about different spiders, particularly with necrotic arachnidism. For example, cutaneous anthrax was mistaken for a cutaneous necrotic spider bite.¹⁹¹ Additionally, the white tail spider (*Lampona* spp) was suspected for more than 20 years to cause necrotic lesions. Only recently has a prospective study of confirmed spider bites refuted this myth by reporting more than 700 confirmed spider bites in Australia.^{127,128,129} Because most arthropod-focused research involves characterizing the structure of spider toxins rather than verifying clinical presentations, it is important to produce clinical studies that have bites confirmed by the presence of the spider that is identified by an expert. Definite spider bites or stings are defined as the following: (1) evidence of a bite or sting soon after the incident or the creature can be seen to bite or sting, (2) collection of the particular creature, either alive or dead, with positive identification of the creature by an expert biologist/taxonomist in the field relating to the creature.^{128,130}

BLACK WIDOW SPIDER (*LATRODECTUS MACTANS*; HOURGLASS SPIDER)

Five species of widow spiders are found in the United States: *Latrodectus mactans* (black widow; Fig. 118–2A), *Latrodectus hesperus* (Western black widow), *Latrodectus variolus* (found in New England, Canada, south to Florida, and west to eastern Texas, Oklahoma, and Kansas), *Latrodectus bishopi* (red widow of the South), and *Latrodectus geometricus* (brown widow or brown button spider; Fig. 118–2B). They are present in every state except for Alaska. Dangerous widow

spiders in other parts of the world include *L. geometricus* and *Latrodectus tredecimguttatus* (European widow spider found in southern Europe), *Latrodectus hasselti* (red-back widow spider found in Australia, Japan, and India; [Fig 118-2C](#)), and *Latrodectus cinctus* (found in South Africa). These spiders live in temperate and tropical latitudes in stone walls, crevices, wood piles, outhouses, barns, stables, and rubbish piles. They molt multiple times and as a result can change colors. The ventral markings on the abdomen are species specific, and the classic red hourglass-shaped marking is noted in only *L. mactans*. Other species may have variations on their ventral surface, such as triangles and spots.

FIGURE 118-2 Widow spiders. (A) The North American black widow spider, *Latrodectus mactans*. Note the hourglass on the abdomen. (B) The brown widow spider, *Latrodectus geometricus*. (C) The Australian redback spider, *Latrodectus hasselti*. (Used with permission of The American Museum of Natural History.)

Typically, the female *L. mactans* is shiny, jet-black, and large (8–10 mm), with a rounded abdomen and a red hourglass mark on its ventral surface. Her larger size and ability to penetrate human skin with her fangs make her more venomous and toxic than the male spider, which resembles the immature spider in earlier stages of development and is smaller, lighter in color, and has a more elongated abdomen and fangs that usually are too short to envenomate humans ([Table 118-3](#)). Black widow females are trappers and inhabit large, untidy, irregularly shaped webs. Webs are placed in or close to the ground and in secluded, dimly lit areas that can trap flying insects, such as outdoor privies, barns, sheds, and garages.⁵

TABLE 118-3. Brown Recluse and Black Widow Spiders: Comparative Characteristics

	<i>Brown Recluse (Larsscoles spp)</i>	<i>Black Widow (Latrodectus spp)</i>
Description	Female brown, 6–20 mm, violin shaped mark on dorsum of cephalothorax; female greater toxicity than male	Female jet black, 8–10 mm, red hourglass mark on ventral surface, female greater toxicity than male
Major venom component	Sphingomyelinase D	α -Latrotoxin
Pathophysiology of envenomation	Vascular injury, dermatonecrosis, hemolysis	Massive presynaptic discharge of neurotransmitters; lymphatic and hematogenous spread, neurotoxicity
Epidemiology	Bites more common in warmer months North America (southern and midwestern states): <i>L. reclusa</i> South America: <i>L. loati</i> , <i>L. guschi</i> Europe: <i>L. rufescens</i> Africa (southern): <i>L. parum</i> , <i>L. spiniceps</i> , <i>L. pilosa</i> , <i>L. bergeri</i> Asia/Australia: Rare	Bites more common in warmer months in subtropical and temperate areas; perennial in tropics North America: <i>L. mactans</i> , <i>L. hesperus</i> , <i>L. geometricus</i> Europe: <i>L. tenebrosus</i> Africa (southern): <i>L. indistinctus</i> Australia: <i>L. hasselti</i> Asia/South America: Rare
Clinical effects	Cutaneous Initial (0–2 hours after bite): Painless, erythema, edema 2–8 hours: Hemorrhagic, ulcerates, painful 1 week: Eschar Months: Healing Hematologic Methemoglobinemia, hemolysis, thrombocytopenia, disseminated intravascular coagulopathy Renal: Kidney failure, acute tubular necrosis	Cutaneous Initial (5 minutes–1 hour after bite): Local pain 1–2 hours: Puncture marks Hours: Regional lymph nodes swollen, central blanching at bite site with surrounding erythema CVS: Initial tachycardia followed by bradycardia, dysrhythmias, initial hypotension followed by hypertension GI: Nausea, vomiting, mimic acute abdomen Hematologic: Leukocytosis Resolution over several days Metabolic Hyperglycemia (transient) Musculoskeletal: Hypertonia, abdominal rigidity, "facies latrodectimica" Neurologic CNS: Psychosis, hallucinations, visual disturbance, seizures Peripheral nervous system: Pain at the site Autonomic nervous system: Increased secretions; sweating, salivation, lacrimation, diarrhea, bronchorrhea, mydriasis, miosis, priapism, ejaculation Renal: Glomerulonephritis, oliguria, anuria Respiratory: Bronchoconstriction, acute respiratory distress syndrome
Treatment	Analgesia Wound care Dapsone (?) Hyperbaric oxygen (local) (?) Antivenom (?) not available universally Corticosteroids	Analgesia Muscle relaxants Antivenom

Pathophysiology

The venom is more potent on a volume-per-volume basis than the venom of a pit viper and contains six active components with molecular weights of 5000 to 130,000 Da.⁵ The six components are five latroinsectotoxins (α -, β -, γ -, δ -, ϵ -LITs) (insect-specific neurotoxins), and α -latrocrustatoxin (α -LCT) (crustacean-specific neurotoxin).¹⁰⁵ α -Latrotoxin binds, with nanomolar affinity, to the specific presynaptic receptors neurexin I- α and Ca^{2+} -independent receptor for α -latrotoxin (CIRL), otherwise known as latrophilin.^{30,114,126} The binding triggers a cascade of events: conformational change allowing

pore formation by tethering the toxin to the plasma membrane; Ca^{2+} ionophore formation; translocation of the N-terminal domain of α -LTX into the presynaptic intracellular space, and intracellular activation of exocytosis of norepinephrine, dopamine, neuropeptides, acetylcholine, glutamate, and γ -aminobutyric acid (GABA), respectively. This massive release of neurotransmitters is what causes the clinical envenomation syndrome known as latrodectism.^{5,171,174}

Clinical Manifestations

Widow spiders are shy and nocturnal. They usually bite when their web is disturbed or upon inadvertent exposure in shoes and clothing. A sharp pain typically described as a pinprick occurs as the victim is bitten. A pair of red spots may evolve at the site, although the bite is commonly unnoticed.^{53,155} The bite mark itself tends to be limited to a small puncture wound or wheal and flare reaction that often is associated with a halo (Table 118–3). However, the bite from *L. mactans* may produce latrodectism, a constellation of signs and symptoms resulting from systemic toxicity. Some cases do not progress; others may show severe neuromuscular symptoms within 30 to 60 minutes. The effects from the bite spread contiguously. For example, if a person is bitten on the hand, the pain progresses up the arm to the elbow, shoulder, and then toward the trunk during systemic poisoning. Typically, a brief time to symptom onset denotes severe envenomation. One patient developed latrodectism following the intentional intravenous injection of a crushed whole black widow spider.⁴⁷

One grading system divides the severity of the envenomation into three categories.⁶⁰ Grade 1 envenomations range from no symptoms to local pain at the envenomation site with normal vital signs. Grade 2 envenomations involve muscular pain at the site with migration of the pain to the trunk, diaphoresis at the bite site, and normal vital signs. Grade 3 envenomations include the grade 2 symptoms with abnormal vital signs; diaphoresis distant from the bite site; generalized myalgias to back, chest, and abdomen; and nausea, vomiting, and headache.

The myopathic syndrome of latrodectism involves muscle cramps that usually begin 15 minutes to 1 hour after the bite. The muscle cramps initially occur at the site of the bite but later may involve rigidity of other skeletal muscles, particularly muscles of the chest, abdomen, and face. The pain increases over time and occurs in waves that may cause the patient to writhe. Large muscle groups are affected first. Classically, severe abdominal wall spasm occurs and may be confused with a surgical abdomen, especially in children who cannot relate the history with the initial bite.⁴⁴ Muscle pain often subsides within a few hours but may recur for several days. Transient muscle weakness and spasms may persist for weeks to months.

Additional clinical findings include “*facies latrodectismica*,” which consists of sweating, contorted, grimaced face associated with blepharitis, conjunctivitis, rhinitis, cheilitis, and trismus of the masseters.¹⁵⁵ A fear of death, *pavor mortis*, is described.¹⁵⁵ Nausea, vomiting, sweating, tachycardia, hypertension, muscle cramping, restlessness, compartment syndrome at the site of the bite, and, rarely, priapism are also reported.^{5,61,119,214} The mechanism of compartment syndrome developing after a black widow spider envenomation is unclear, but two postulated theories include rhabdomyolysis and the venom affecting the blood vessels leading to engorgement and obstruction of the venous outflow. In one case, the compartment syndrome was treated with antivenom, and the patient recovered without the need for a fasciotomy.⁶¹ Recovery usually ensues within 24 to 48 hours, but symptoms may last several days with more severe envenomations. Life-threatening complications include severe hypertension, respiratory distress, myocardial infarction, cardiovascular failure, and gangrene.^{47,60,61,81,165,179,183} In the past 20 years, more than 40,000 presumed black widow spider bites have been reported to the American Association of Poison Control Centers. Death is rarely reported. There have been two fatalities in Madagascar from envenomation by *L. geometricus*, one from cardiovascular failure and the other from gangrene of the foot.¹⁸³ The most recent fatality reported from Greece resulted from myocarditis secondary to envenomation by *L. tredecimguttatus*,¹⁸² confirmed by a local veterinarian. The patient developed severe dyspnea, hypoxemia, cyanosis, cardiomyopathy, and global hypokinesia of the left ventricle confirmed by echocardiography, followed by death 36 hours later; antivenom was not available. On autopsy, diffuse interstitial and alveolar edema, with mononuclear infiltrate of the myocardium and degenerative changes, were noted, and toxicologic analysis for xenobiotics, as well as all blood, urine, bronchial, and serologic viral cultures, were negative. The paucity of mortalities is presumed to result from the improvement in medical care, the availability of antivenom, or the limited toxicity of the spider.

Diagnostic Testing

Laboratory data generally are not helpful in management or predicting outcome. According to one study, the most common findings include leukocytosis and increased creatine phosphokinase and lactate dehydrogenase concentrations.⁶⁰ Currently, no specific laboratory assay is capable of confirming latrodectism. However, the clinical situation may warrant the need to check laboratory tests and other studies to evaluate the sequelae of the black widow spider envenomation.

Management

Treatment involves establishing an airway and supporting respiration and circulation, if indicated. Wound evaluation and local wound care, including tetanus prophylaxis, are essential.²³⁶ The routine use of antibiotics is not recommended.

Pain management is a substantial component of patient care and depends on the degree of symptomatology. Using the grading system, grade 1 envenomations may require only cold packs and orally administered nonsteroidal antiinflammatory agents. Grade 2 and 3 envenomations probably require intravenous (IV) opioids and benzodiazepines to control pain and muscle spasm.

Traditionally, 10 mL 10% calcium gluconate solution was given IV to decrease cramping. However, a retrospective chart review of 163 patients envenomated by the black widow concluded that calcium gluconate was ineffective for pain relief compared with a combination of IV opioids (morphine sulfate or meperidine) and benzodiazepines (diazepam or lorazepam).^{60,141} Another study found greater neurotransmitter release when extracellular calcium concentrations were increased, suggesting that administration of calcium is irrational in patients suffering from latrodectism.¹⁹² The mechanism of action of calcium remains unknown, and its efficacy is anecdotal; therefore, we do not recommend calcium administration for pain management.

Although often recommended, methocarbamol (a centrally acting muscle relaxant) and dantrolene also are ineffective for treatment of latrodectism.^{141,197} A benzodiazepine, such as diazepam, is more effective for controlling muscle spasms and achieves sedation, anxiolysis, and amnesia. Management should primarily emphasize supportive care, with opioids and benzodiazepines for controlling pain and muscle spasms, because the use of antivenom risks anaphylaxis and serum sickness.

Latrodectus antivenom (Wyeth) is rapidly effective and curative. In the United States, the antivenom formulation is effective for all species but is available as a crude hyperimmune horse serum that may cause anaphylaxis and serum sickness. The morbidity of latrodectism is high, with pain, cramping, and autonomic disturbances, but mortality is low. Hence controversy exists over when to administer the black widow antivenom. The antivenom can be administered for severe reactions (eg, hypertensive crisis or intractable pain), to high-risk patients (eg, pregnant women suffering from a threatened abortion), or for treatment of priapism.^{141,183} Use of antivenom probably should not be considered for patients unless systemic effects are designated as grade 3.⁶¹ The usual dose is one to two vials diluted in 50 to 100 mL 5% dextrose or 0.9% sodium chloride solution, with the combination infused over 1 hour (Antidotes in Depth: A34). Skin testing may identify a highly allergic individual but does not eliminate the occurrence of hypersensitivity reactions; therefore, we do not recommend skin testing. Recently, an anaphylactoid reaction to the black widow spider antivenin was reported after a negative skin test in both a boy and a man^{124,168} who subsequently died from the anaphylactoid reaction. Both were being treated for intractable pain after failing intravenous opioid management. Pretreatment with histamine H₁- or H₂-blockers, or both, and epinephrine may be beneficial in preventing histamine release and anaphylaxis. Patients with allergies to horse serum products and those who have received antivenom or horse serum products are at risk for immunoglobulin IgE-mediated hypersensitivity reactions and, though efficacy is largely unproven, may benefit from the pretreatment with antihistamines and corticosteroids.

A purified F(ab)₂ fragment *Latrodectus mactans* antivenom, Analatro®, is currently undergoing clinical trials (Antidotes in Depth: A34).

In Australia, a purified equine-derived IgG-F(ab)₂ fragment antivenom for the red-back spider *L. hasselti* (RBS-AV) is available. The RBS-AV (CSL, Melbourne, Australia) is administered intramuscularly and given as first-line therapy to patients presenting with systemic signs or symptoms in Australia. Since its introduction in 1956, no deaths are reported, and the incidence of mild allergic reactions to RBS-AV is only 0.54% in 2144 uses.²²³

However, an underpowered prospective cohort study of confirmed red-back spider bites failed to show that intramuscular antivenom was better than no treatment when all patients were followed up over one week.¹²⁹ This study did note that only 17% of patients were pain-free at 24 hours with antibody treatment. Therefore, intramuscular antivenom appears to be less effective than previously thought, and the route of administration requires review. Recently in Italy, an FM₁ Fab fragment specific for the α-latrotoxin has been highly effective in neutralizing the toxin in vivo in mice and shows some promise for possible use in humans.^{12,45} This single monoclonal antibody shows great promise in the treatment for severe black widow envenomation. Inadvertent use of RBS-AV successfully treated envenomations from the comb-footed spider (*Steatoda* spp),¹³⁰ and the *Steatoda* venom and clinical effects are similar to the *Latrodectus* venom but milder in clinical presentation.¹⁰³

BROWN RECLUSE SPIDER (*LOXOSCELES RECLUSA*; VIOLIN OR FIDDLEBACK SPIDER)

Loxosceles reclusa was confirmed to cause necrotic arachnidism in 1957, although reports of systemic symptoms following brown spider bites have appeared since 1872.¹⁰ This spider has a brown violin-shaped mark on the dorsum of the cephalothorax, three dyads of eyes arranged in a semicircle on top of the head, and legs that are five times as long as the body. It is small (6–20 mm long) and gray to orange or reddish brown (Fig. 118–3A). *Loxosceles* spiders weave irregular white, flocculent adhesive webs that line their retreats.⁹² Spiders in the genus *Loxosceles* have a worldwide distribution. In

the United States, other species of this genus, which include *L. rufescens*, *L. deserta*, *L. devia*, and *L. arizonica*, are prominent in the Southeast and Southwest.⁹ *L. rufescens* was inadvertently introduced in several buildings in New York City. Though it is unclear how they initially arrived there, they were most likely transported on personal belongings and cartons of materials (confirmed by Lou Sorkin BCE, arachnologist, American Museum Natural History, New York).²¹¹ They are hunter spiders that live in dark areas (wood piles, rocks, basements), and their foraging is nocturnal. They are not aggressive but will bite if antagonized (Table 118-3). These spiders live up to 2 years and maybe even longer. They are resilient and can survive up to 6 months without water or food and can tolerate temperatures from 46.4° to 109.4°F (8°–43°C).⁹⁶ Like the black widow spider, the female is more dangerous than the male. *Loxosceles* venom has variable toxicity, depending on the species, with *Loxosceles intermedia* venom causing more severe clinical effects in humans.^{15,16} The peak time for envenomation is from spring to autumn, and most victims are bitten in the morning. However, the brown recluse spider is often misdiagnosed as the culprit for a necrotic wound and has been identified as the biting spider when *L. rufescens* was the actual species. One study examined 182 patients enrolled over 23 months who presented to the emergency department (ED) for a chief complaint of spider bite. The study found that only 3% (7/182) were ultimately confirmed by their treating physician to have the diagnosis of a spider bite, whereas 84% (152/182) had a skin and soft tissue infection (SSTI), nine patients were bitten by other animals, six patients were given other non-bite diagnoses, such as erythema multiforme, subcutaneous nodules, folliculitis from a razor cut, and eight patients had no diagnostic category recorded. Of the seven patients that had a confirmed spider bite, only one brought the spider in for identification, while the others saw a spider or witnessed a bite, and one patient did not witness or feel a bite.²¹⁷ Community-acquired MRSA was the most common cause of SSTI's, accounting for 70% of positive wound cultures when performed. Hence the spider bite diagnosis is often frequently misused, and a diagnosis of dermatonecrotic wound of uncertain etiology would be more accurate.²¹⁷

FIGURE 118-3 Brown recluse spider. (A) *Loxosceles reclusa*. Note the image of the violin, which gives the spider its common name, “the fiddle back spider.” (Image contributed by Progeny Products, www.brown-recluse.com.) (B) A typical

envenomation from the brown recluse spider. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Pathophysiology

The venom is cytotoxic. The two main constituents of the venom are sphingomyelinase-D and hyaluronidase, though other subcomponents include deoxyribonuclease, ribonuclease, collagenase, esterase, proteases, alkaline phosphatase, and lipase.^{70,146,232} Hyaluronidase is a spreading factor that facilitates the penetration of the venom into tissue but does not induce lesion development.¹⁴⁶ Sphingomyelinase-D is the primary constituent of the venom that causes necrosis and red blood cell hemolysis and also causes platelets to release serotonin.¹⁴⁶ Sphingomyelinase also reacts with sphingomyelin in the red blood cell membrane to release choline and N-acylsphingosine phosphate, which triggers a chain reaction releasing inflammatory mediators, such as thromboxanes, leukotrienes, prostaglandins, and neutrophils, leading to vessel thrombosis, tissue ischemia, and skin loss.¹⁴⁶ Early perivascular collections of polymorphonuclear leukocytes with hemorrhage and edema progress to intravascular clotting. Coagulation and vascular occlusion of the microcirculation occur, ultimately leading to necrosis.²⁰⁷

Clinical Manifestations

The clinical spectrum of loxoscelism can be divided into three major categories. The first category includes bites in which very little, if any, venom is injected. A small erythematous papule may be present that becomes firm before healing and is associated with a localized urticarial response. In the second category, the bite undergoes a cytotoxic reaction. The bite initially may be painless or have a stinging sensation but then blisters and bleeds and ulcerates 2 to 8 hours later (Table 118–3). The lesion may increase in diameter, with demarcation of central hemorrhagic vesiculation, then ulcerates and develops violaceous necrosis, surrounded by ischemic blanching of skin and outer erythema and induration over 1 to 3 days. This is also known as the “red, white, and blue” reaction (Fig. 118–3B).^{142,242} Necrosis of the central blister occurs in 3 to 4 days, with eschar formation between 5 and 7 days. After 7 to 14 days, the wound becomes indurated and the eschar falls off, leaving an ulceration that heals by secondary intention. Local necrosis is more extensive over fatty areas (thighs, buttocks, and abdomen).¹⁴⁶ The size of the ulcer determines the time for healing. Large lesions up to 30 cm may require months or more to heal.

Upper airway obstruction was reported in a child who was bitten on his neck and subsequently developed progressive cervical soft tissue edema with airway obstruction and dermatonecrosis 40 hours later.¹⁰⁰ Another case reported stridor and respiratory distress following a brown recluse envenomation of the ear. Although the presentation is rare, respiratory compromise should be considered when an envenomation occurs near the airway.⁹⁵

The third category consists of systemic loxoscelism, which is not predicted by the extent of cutaneous reaction, and occurs 24 to 72 hours after the bite. The young are particularly susceptible.^{99,198} The clinical manifestations of systemic loxoscelism include fever, chills, weakness, edema, nausea, vomiting, arthralgias, petechial eruptions, rhabdomyolysis, disseminated intravascular coagulation, hemolysis that can lead to hemoglobinemia, hemoglobinuria, acute kidney injury, and death.^{27,49,88,99,153,202,239} However, in North America, the incidence of systemic illness is rare, and mortality is low.⁷

Diagnostic Testing

Bites from other spiders, such as Cheiracanthium (sac spider), Phidippus (jumping spider), and Argiope (orb weaver), can produce necrotic wounds. These spiders are often the actual culprits when the brown recluse is mistakenly blamed. Definitive diagnosis is achieved only when the biting spider is positively identified. No routine laboratory test for loxoscelism is available for clinical application, but several techniques are presently used for research purposes. The lymphocyte transformation test measures lymphocytes that have undergone blast transformation up to one month after exposure to *Loxosceles* venom. The lymphocytes incorporate thymidine into the nucleoprotein, providing a quantitative response.⁸ A passive hemagglutination inhibition test (PHAI) has been developed in guinea pigs. The PHAI assay is based on the property of certain brown recluse spider venom components to spontaneously adsorb to formalin-treated erythrocyte membranes and the ability of the brown recluse spider venom to inhibit antiserum-induced agglutination of venom-coated red blood cells.¹⁸ The test is 90% sensitive and 100% specific for 3 days postenvenomation and may prove useful for early diagnosis of brown recluse spider envenomation.¹⁸ An enzyme-linked immunoassay (ELISA) specific for *Loxosceles* venom in biopsied tissue can confirm the presence of venom for 4 days postenvenomation,¹⁸ and in an experimental model using rabbits, the antigen was recoverable using the ELISA assay from 14 to 21 days.¹⁵⁸ The drawbacks of using a skin biopsy are the invasive nature of the procedure, which can result in further scarring with an increased potential for infection, and the lack of proof that skin biopsy can diagnose early envenomations prior to the development of dermatonecrosis. Another ELISA utilizing serum for detection of venom antigens has been developed that correctly discriminates the mice inoculated with antigens from *L. intermedia* venom. The ELISA immunoassay and antivenom may

become useful diagnostic tools if envenomation can be proved or disproved early.⁵⁷ A venom-specific enzyme immunoassay that uses hair, skin biopsies, or aspirated tissue near a suspected lesion to detect the presence of venom up to 7 days after injury is under investigation.^{145,161} In Brazil, ELISA is used to detect the venom of *Loxosceles gaucho* in wounds and patient sera, but the technique is not in widespread clinical use.⁵³

Clinical laboratory data may be remarkable for hemolysis, hemoglobinuria, and hematuria. Coagulopathy may be present, with laboratory data significant for elevated fibrin split products, decreased fibrinogen concentrations, and a positive D-dimer assay. Other tests may show increased prothrombin time (PT) and partial thromboplastin time (PTT), leukocytosis (up to 20,000–30,000 cells/mm³), spherocytosis, Coombs-positive hemolytic anemia, thrombocytopenia, or abnormal kidney and liver function tests.^{5,12,92,194,196,198,237}

Treatment

Optimal local treatment of the lesion is controversial. The most prudent management of the dermatonecrotic lesion is wound care, immobilization, tetanus prophylaxis, analgesics, and antipruritics as warranted (Table 118–4).^{5,92,234,237} Early excision or intralesional injection of corticosteroids appears unwarranted.¹⁸⁹ Corrective surgery can be performed several weeks after adequate tissue demarcation has occurred. In one case series the use of curettage of the lesion to remove necrotic and indurated tissue from the lesion, thus eliminating any continuing action of the lytic enzymes on the surrounding tissue, showed promising results.¹¹⁷ These patients had wound healing without further necrosis and minimal scarring. Vacuum-assisted closure, otherwise known as negative pressure wound therapy, is also described in a series of clinical cases in the surgical literature as a means to treat necrotic wounds caused by presumed brown recluse spider bites more quickly than the traditional methods, due to increased bacterial clearance and dermal perfusion, modulating the inflammatory response, extracting toxic substances, and accelerated rate of granulation tissue formation.²⁴⁰ Electric shock delivered via stun guns was not found to be useful in a guinea pig envenomation model.¹⁸ Cyproheptadine, a serotonin antagonist, was not beneficial in a rabbit model.¹⁷⁶ A randomized, controlled study evaluating the efficacy of topical nitroglycerin for envenomated rabbits showed no difference in preventing skin necrosis and suggested the possibility of increased systemic toxicity.¹⁵⁰ Antibiotics should be used to treat cutaneous or systemic infection, but they should not be used prophylactically.

TABLE 118–4. Management of Brown Recluse Spider Bite

General Wound Care	Local Wound Care	Systemic
Clean	Serial observations	Antipruritic/antianxiety and/or analgesics
Tetanus prophylaxis as indicated	Natural healing by granulation	Antibiotics for secondary bacterial infection
Immobilize and elevate bitten extremity	Delayed primary closure	Polymorphonuclear white blood cell inhibitors (?): dapsone, colchicine
Apply cool compresses; avoid local heat	Delayed secondary closure with skin graft Gauze packing, if applicable	Antivenom (experimental) Hyperbaric oxygen (local) (?)

Early use of dapsone (in patients who develop a central purplish bleb or vesicle within the first 6–8 hours) may inhibit local infiltration of the wound by polymorphonuclear leukocytes.¹⁴² The dosage recommended is 100 mg twice daily for 2 weeks.¹⁸⁷ However, prospective trials with large numbers of patients are lacking. One study compared the efficacy of erythromycin and dapsone therapy, erythromycin and antivenom therapy, and erythromycin, dapsone, and antivenom therapy (developed in rabbits based on a previous study).¹⁸⁶ Although the treatment groups were very small, all groups showed wound healing at approximately 20 days despite the different therapies used. This study’s biggest limitation includes the definition of a spider bite diagnosis (the study used the following criteria: a patient feeling the spider bite, seeing the spider, or having a clinically plausible necrotic lesion). The study suggests that the use of dapsone may eliminate the need for surgery following bites and that antivenom therapy was most effective clinically if the patient never developed the necrotic lesion. Hence, the use of dapsone in the management of a local lesion should be considered experimental until its use is validated by randomized, controlled clinical trials. Hepatitis,¹⁹⁰ methemoglobinemia (Chap. 127), and hemolysis are associated with dapsone use. If dapsone therapy is used, a baseline glucose-6-phosphate dehydrogenase and weekly complete blood counts should be performed.

An underpowered animal study evaluated the effects on the size of skin lesions induced by *Loxosceles* envenomation by treatment with hyperbaric oxygen therapy, dapsone, and combined hyperbaric oxygen therapy and dapsone.¹¹⁵ The study concluded that there was no clinically significant change in necrosis or induration by these treatment modalities. Further evaluation of these interventions remains appropriate. Another study using hyperbaric oxygen for treatment of *Loxosceles*-induced necrotic lesions in rabbits revealed no clinical improvement in the size of the lesion; however, the histology of the lesions improved. Whether this finding is of value in humans has not been determined.^{115,216} Use of 1.2 mg colchicine, a leukocyte inhibitor, followed at 2-hour intervals with 0.6 mg for 2 days, then 0.6 mg every hours for 2 additional days is sometimes recommended, but we do not advocate this treatment because of potential colchicine toxicity.¹⁹⁴ Rabbit-derived intradermal anti-*Loxosceles* Fab (α -Loxd) fragments attenuated the dermatonecrotic inflammation of rabbits injected with *L. deserta* venom in a time-dependent fashion.⁹⁷ At time 0 after envenomation, lesion development was blocked. At time 1 and 4 hours after envenomation, the α -anti-Loxd Fab antivenom continued to suppress the lesion areas, although the longer the delay in treatment, the smaller the difference in treatment and control lesion areas. At time 8 and 12 hours postenvenomation, there was no difference in lesion size. The typical 24-hour delay in lesion development makes the diagnosis difficult, and the antivenom would likely be useless if administered so late in the clinical course. Currently this antivenom is not available for commercial use.

One preclinical study shows promise for the treatment of *Loxosceles* envenomations using an antiloxoscelic serum that was produced from recombinant sphingomyelinase D that was derived from the sphingomyelinase of the *L. intermedia* and *L. laeta* spiders. The isolated sphingomyelinase from the respective *Loxosceles* species carried the full biological effects of the entire venom. This antiloxoscelic serum when administered IV into rabbits that were given intradermal injections of the loxoscelic venom from *L. laeta* and *L. intermedia* had greater neutralizing activity than when compared to the existing antiarachnid serum, which is made by hyperimmunizing horses against the venom of *L. gaucho*, *P. nigriventer*, and the scorpion *Tityus serrulatus*. In Brazil and South America, most of the envenomations occur with the *L. laeta* and *L. intermedia*, not *L. gaucho*. Knowing which species envenomated the patient could help determine which antiserum should be used.⁷³

Patients manifesting systemic loxoscelism or those with expanding necrotic lesions should be admitted to the hospital. All patients should be monitored for evidence of hemolysis, acute kidney injury, or coagulopathy. If hemoglobinuria ensues, increased IV fluids and urinary alkalization can be used in an attempt to prevent acute kidney injury. Hemolysis, if significant, can be treated with transfusions. Patients with coagulopathy should be monitored with serial complete blood cell count, platelet count, PT, PTT, fibrin split products, and fibrinogen. Disseminated intravascular coagulopathy may require treatment, based on severity.

HOBO SPIDER (TEGENARIA AGRESTIS, NORTHWESTERN BROWN SPIDER, WALCKENAER SPIDER)

The hobo spider is native to Europe and was introduced to the northwestern United States (Washington, Oregon, Idaho) in the 1920s or 1930s.²³³ These spiders build funnel-shaped webs within wood piles, crawl spaces, basements, and moist areas close to the ground. They are brown with gray markings and 7 to 14 mm long. They are most abundant in the midsummer through the fall. They bite if provoked or threatened but otherwise retreat quickly with disturbance.²³ The medical literature is sparse in reported hobo spider bites that are verified by a specialist. There is only one confirmed Hobo spider bite resulting in a necrotic lesion.⁶³ A 42 year-old woman with a history of phlebitis who felt a burning sensation on her ankle rolled her pants and found a crushed brown spider, which was later confirmed (unpublished source cited by MMWR) to be *T. agrestis*. She complained of persistent pain, nausea, and dizziness, and a vesicular lesion developed within several hours. The vesicle ruptured and ulcerated the next day. The lesion initially was 2 mm, but over the next 10 weeks enlarged to 30 mm in diameter and was circumscribed with a black lesion, at which time she sought medical advice. She was given a course of antibiotics, which did not limit the progression of this ulcer. Subsequently, the patient was unable to walk, and she was found to have a deep venous thrombosis. The other cases implicating Hobo spiders as a cause for dermatonecrotic injuries are based on proximity of the Hobo spider or other large brown spiders that are unidentified. *T. agrestis* venom implanted into rabbit skin can produce hemorrhagic necrotic lesions dermally and systemically.^{233,234}

The venom from European Hobo spiders and US Hobo spiders was analyzed using liquid chromatography to address the question of variability between the two spiders. *T. agrestis* originating from Europe is considered medically harmless. Liquid chromatography (European Hobo *T. agrestis* from the United Kingdom and American Hobo *T. agrestis* from Washington State, United States) found little variability between the two venoms to account for their differential necrotic effects.²⁸ The authors suggest four possibilities for the discrepancy between the European Hobo and American Hobo spiders: (1) an evolutionary change may have accounted for the novel necrotic effects; (2) venom chemistry may be similar but the habitat might account for the difference in behavior; (3) venom chemistry and habitat may be similar but an extrinsic factor such as a bacterium found in the US Hobo spider might be the cause for the necrotic effects; (4) *T. agrestis* do not

directly or indirectly cause necrotic arachnidism and have been falsely accused.²⁸ The authors suggest that either a bacterium such as *Mycobacterium ulcerans*, known to cause slow-developing ulcers on human skin, might coexist on the chelicerae of the *T. agrestis*, which is highly unlikely because of the presence of antibacterial peptides in the venom,^{113,241} or the more likely circumstance that *T. agrestis* has been falsely accused as being a cause for necrotic arachnidism. Further evidence to suggest that the *T. agrestis* is not likely to be a culprit for necrotic arachnidism is based on a study that evaluates the possibility of the spider's ability to carry and transfer pathogenic bacteria including the methicillin-resistant *Staphylococcus aureus* (MRSA) and analyzes the venom's hemolytic properties.⁹¹ One hundred two *T. agrestis* adult spiders were collected, and a bacterial diversity assay was conducted to find a total of six Gram-positive and four Gram-negative bacteria genera identified which was consistent with the bacteria found in the fauna of the natural environment of the Pacific Northwest and several occurring on human and animal skin. Spiders were then exposed to MRSA on polyethylene disks since the tissue lesions caused by this bacterium is often confounded with a necrotic arachnidism. No MRSA was found on either the spiders or the surfaces to which the MRSA exposed spiders were subjected, although the MRSA was found to persist on the polyethylene disks. Finally, the Hobo Spider venom was analyzed to determine its hemolytic activity in vertebrate blood. Compared to the known *Loxocles reclusa* hemolytic activity of 37%, the potential of *T. agrestis* venom hemolysis activity was negligible at 0.62 and 0.93% for male ($n = 5$) and female ($n = 7$) spiders, respectively. Misdiagnosis of spider bites is common. Wounds can be misleading and can occur from the reaction of other organisms such as ticks and other arthropods, superinfection with anthrax, or underlying medical conditions like diabetes and leukemia or bacterial infections. The need to revisit the Hobo spider toxicity syndrome with further studies that show direct evidence of *T. agrestis* causing necrotic arachnidism in humans is warranted before one can conclude that any necrotic arachnidism in the Pacific Northwest is caused by *T. agrestis*.

Pathophysiology

The toxin has been fractionated, with three peptides identified as having potent insecticidal activity and no discernible effects in mammalian in vivo assays.¹³⁴ The peptide toxins TaITX-1, TaITX-2, and TaITX-3 exhibit potent insecticidal properties by acting directly in the insect central nervous system and not at the neuromuscular junction.¹³⁴ Insects envenomated with *T. agrestis* venom and the insecticidal toxins purified from the venom developed a slowly evolving spastic paralysis. Currently, little is known about the toxin and its mechanism of action in humans.

Clinical Manifestations

The toxicity of Hobo spider venom is questionable; however, it occasionally causes necrosis secondary to infection. Other causes of dermatonecrotic lesions should be considered. The most common symptom associated with the spider bite is a headache that may persist for one week.⁶³ Other symptoms, including nausea, vomiting, fatigue, memory loss, visual impairment, weakness, and lethargy, are reported.^{63,234}

Diagnostic testing

No specific laboratory assay confirms envenomation with *T. agrestis* spider.

Treatment

Treatment emphasizes local wound care and tetanus prophylaxis, although systemic corticosteroids for hematologic complications may be of value. Surgical graft repair for severe ulcerative lesions may be warranted when there is no additional progression of necrosis.⁶³

TARANTULAS

Tarantulas are primitive mygalomorph spiders that belong to the family Theraphosidae, a subgroup of Mygalomorphae (Greek word mygale for field mouse).^{58,200} There are more than 1500 species, with 54 species found in the deserts of the western United States.¹⁷⁸ Because of their great size and reputation, tarantulas are often feared. They are the largest and hairiest spiders, popular as pets, and can be found throughout the United States as well as in tropical and subtropical areas (Fig. 118–4). The lifespan of the female can exceed 15 to 20 years. They have poor eyesight and usually detect their victims by touch and vibrations. Their defense lies in either their painful bite with erect fangs or by barraging their victim with urticating hairs that are released on provocation.⁵⁸ Only the New World tarantulas (tarantulas indigenous to the Americas) have and use the urticating hairs to defend themselves.⁵⁸

FIGURE 118-4 The Mexican redknee tarantula, *Brachypelma smithi*. (Used with permission of The American Museum of Natural History.)

Tarantulas may bite when provoked or roughly handled. Based on the few case reports, their venom has relatively minor effects in humans but can be deadly for canines and other small animals, such as rats, mice, cats, and birds.^{44,131} Small prey might actually be killed by the physical nature of having fangs impaled many times through their bodies. A study from Australia covering a 25 year span reported only nine confirmed bites by Theraphosid spiders in humans and seven confirmed bites in canines—in two cases the owner was bitten after the dog.^{19,131} At least four genera of tarantulas (*Lasiadora*, *Grammostola*, *Acanthoscurria*, and *Brachypelma*) possess urticating hairs that are released in self-defense when the tarantulas rub their hind legs against their abdomen rapidly to create a small cloud.⁹⁶ There are seven different types of urticating hairs. Type 1 hairs are found on tarantulas in the United States and are the only hairs that do not penetrate human skin. Type 2 hairs are incorporated into the silk web retreat but are not thrown off by the spider. Type 3 hairs can penetrate up to 2 mm into human skin. Type 4 hairs belong to the South American *Grammostola* spider and can cause severe respiratory inflammation. Urticarial hairs or setae are composed of chitin, lipoproteins, and mucopolysaccharides, which are recognized as foreign bodies triggering a humoral response in the mammalian immune system. Chitin is proinflammatory and activates T helper cells to stimulate activated macrophages to produce chitinases, which will break down the chitin but also trigger inflammation. Besides cell-mediated inflammation, spider setae can also trigger immunoglobulin E-mediated hypersensitivity.^{19,55}

Pathophysiology

Tarantula venom, specifically the venoms of *Aphonopelma hentzi* (synonym of *Dugesia hentzi* {Arkansas tarantula}) and other members of the genus *Aphonopelma* (Arizona or Texas brown tarantula), contains hyaluronidase, nucleotides (adenosine triphosphate {ATP}, adenosine diphosphate, and adenosine monophosphate), and polyamines (spermine, spermidine, putrescine, and cadaverine) that are used for digesting their prey.^{48,139,200} The role of spermine is unclear, but hyaluronidase is a spreading factor that allows more rapid entrance of venom toxin by destruction of connective tissue and intercellular matrix. ATP potentiates death in mice exposed to the *A. hentzi* venom and lowers the LD₅₀ in comparison to venom without ATP.^{56,155} Both venoms cause skeletal muscle necrosis when injected intraperitoneally into mice.⁹⁰ The primary injury results in rupture of the plasma membrane, followed by the inability of mitochondria and sarcoplasmic reticulum to maintain normal concentrations of calcium in the cytoplasm leading to cell death. *Aphonopelma* venom is similar to scorpion venom in composition and clinical effects. Novel toxins have been discovered in the venom that can act on potassium channels, calcium channels, and the recently discovered acid-sensing ion channels that may elucidate the molecular mechanism of voltage-dependent channel gating and their respective physiologic roles.^{82,83}

Clinical Manifestations

Although relatively infrequent in occurrence, bites present with puncture or fang marks. They range from being painless to a deep throbbing pain that may last several hours without any inflammatory component.¹³¹ Fever occurs in the absence of

infection, suggesting a direct pyrexia action of the venom. Rarely, bites create a local histamine response with resultant itching, and hypersensitive individuals could have a more severe reaction and, less commonly, mild systemic effects such as nausea and vomiting.^{96,131} Contact reactions from the urticating hairs are more likely to be the health hazard than the spider bite. The urticating hairs provoke local histamine reactions in humans and are especially irritating to the eyes, skin, and respiratory tract. Tarantula urticating hairs cause intense inflammation that may remain pruritic for weeks. Inflammation can occur at all levels from conjunctiva to retina. An allergic rhinitis can develop if the hairs are inhaled.¹³⁹ Tarantula hairs resemble sensory setae of caterpillars: both are type 3 that can migrate relentlessly and cause multiple foci of inflammation at all levels of the eye.¹²¹ Ophthalmia nodosa, a granulomatous nodular reaction to vegetable or insect hairs, is reported with casual handling of tarantulas.^{22,26} Other eye findings include setae in the corneal stroma, anterior chamber inflammation, migration into the retina, and secondary glaucoma and cataracts.³¹

Treatment

Treatment is largely supportive. Cool compresses and analgesics should be given as needed. All bites should receive local wound care, including tetanus prophylaxis if necessary. If the hairs are barbed, as in some species, they can be removed by using adhesive such as duct tape or cellophane tape followed by compresses or irrigation with 0.9% sodium chloride solution. If the hairs are located in the eye, then surgical removal may be required, followed by medical management of inflammation. If the hairs are difficult to remove and the patient has persistent ocular pain and discomfort, then a therapeutic pars plana vitrectomy may be necessary to reduce the antigenic load and to improve clinical symptomatology.¹¹⁸ Urticarial reactions should be treated with oral antihistamines and topical or systemic corticosteroids.

FUNNEL WEB SPIDERS

Australian funnel web spiders are a group of large Hexathelidae mygalomorphs that can cause a severe neurotoxic envenomation syndrome in humans. The fang positions of funnel web spiders (as well as the tarantulas) are vertical relative to their body, which requires the spider to rear back and lift the body to attack. The length of fangs can reach up to 5 mm. This spider can bite tenaciously and may require extraction from the victim.¹⁶³ Atrax and Hadronyche species are found along the eastern seaboard of Australia. *A. robustus*, also called the Sydney funnel web spider, is the best known and is located around the center of Sydney, Australia.¹⁶³ Funnel web spiders tend to prefer moist, temperate environments.¹⁶³ They are primarily ground dwellers and live in burrows, crevices in rocks, and around foundations of houses. They build tubular or funnel-shaped webs.⁹⁶ At night, the spiders ascend the tubular web and wait for their prey. The Sydney funnel web spider is considered one of the most poisonous spiders. It was responsible for 14 deaths between 1927 and 1980, at which time the antivenom was introduced.^{220,221}

Pathophysiology

Originally called robustotoxin from *A. robustus* spider and versutoxin from the *Hadronyche versuta* spider, the toxin which is now referred to as atracotoxin or atraxin (δ -ACTX-Arl and δ -ACTX-Hvla, respectively) is the lethal protein component of *A. robustus* venom and is unique in its toxicity affecting primates and newborn mice in biological doses, although other mammals are susceptible in higher doses.^{163,219,221,238} δ -ACTX is a 42 amino acid peptide that targets mammals by increasing the ion conductance at voltage-gated sodium channels via trapping the channel's voltage sensor domain IV S4 segment in an inward conformational change, preventing the closure of the ion channel, thereby evoking a fulminant neurotransmitter release at the autonomic and/or somatic synapses.^{151,172} Hence δ -ACTX produces an autonomic storm, releasing acetylcholine, noradrenaline, and adrenaline. In monkeys, a 5 μ g/kg intravenous infusion dose of robustotoxin from male *A. robustus* spiders causes dyspnea, blood pressure fluctuations leading to severe hypotension, lacrimation, salivation, skeletal muscle fasciculation, and death within 3 to 4 hours.¹⁶⁹ Versutoxin, a toxin from the Blue Mountain funnel web spider, is closely related to robustotoxin and has demonstrated voltage-dependent slowing of sodium channel inactivation.¹⁷³

Clinical Manifestations

A biphasic envenomation syndrome is described in humans and monkeys.^{220,221} Phase 1 consists of localized pain at the bite site, perioral tingling, piloerection, and regional fasciculations (most prominent in the face, tongue, and intercostals). Fasciculations may progress to more overt muscle spasm; masseter and laryngeal involvement may threaten the airway.²¹⁹ Other features include tachycardia, hypertension, cardiac dysrhythmias, nausea, vomiting, abdominal pain, diaphoresis, lacrimation, salivation, and acute respiratory distress syndrome (ARDS), which often is the cause of death in phase 1.²³⁸ Phase 2 consists of resolution of the overt cholinergic and adrenergic crisis; secretions dry up, and fasciculations, spasms, and hypertension resolve. This apparent improvement can be followed by the gradual onset of refractory hypotension,

apnea, and cardiac arrest.²²¹

Treatment

Pressure immobilization using the crepe bandage to limit lymphatic flow and immobilization of the bitten extremity may inactivate the venom and should be applied if symptoms of envenomation are present. Funnel web venom is one of the few animal toxins known to undergo local inactivation. Monkey studies and a human case report support the utility of pressure immobilization.^{101,222} After injecting *A. robustus* venom subcutaneously in monkeys, pressure-immobilization technique increased survival by retarding the venom movement and also by allowing the local peripheral enzymes inactivating the venom.^{220,222}

The patient should be transferred to the nearest hospital with the bandage in place and then stabilized and placed in a resuscitation facility with adequate ampules of antivenom readily available before the bandage is removed; otherwise, a precipitous envenomation may occur during the removal of the pressure bandage. A purified IgG antivenom protective against *Atrax* envenomations was developed in rabbits.²²⁰ One ampule of the antivenom contains 100 mg purified rabbit IgG or 125 units of neutralizing capacity per ampule.²³⁸ It has been effective for more than 40 humans bitten by the *Atrax* species.²²² The starting dose is two ampules if systemic signs of envenomations are present, and four ampules if the patient develops ARDS or decreased mental status. Doses are repeated every 15 minutes until clinical improvement occurs.²³⁸ Up to eight ampules is common in a severe envenomation. Since anaphylaxis has not been reported,²²² the manufacturer no longer recommends premedication. Serum sickness is rare after funnel web antivenom administration, with only one reported case in a patient who received five ampules of antivenom.¹⁶²

SCORPIONS

Scorpions are invertebrate arthropods that have existed for more than 400 million years.⁶² Of the 650 known living species, most of the lethal species are in the family Buthidae (Table 118–5). The genera of the family Buthidae include *Centruroides*, *Tityus*, *Leiurus*, *Androctonus*, *Buthus*, and *Parabuthus*.⁶² Scorpions envenomate humans by stinging rather than biting. Their five-segmented metasoma (“tail”) contains a terminal bulbous segment called the telson that contains the venom apparatus (Fig. 118–5). More than 100,000 medically significant stings likely occur annually worldwide, predominantly in the tropics and North Africa.^{1,25,73,106,132,144} According to American Association of Poison Control Centers data from 1995 to 2011, approximately 11,000 to 19,000 scorpion annual exposures occurred in the United States, mostly in the southwestern region, but no deaths have been reported. These members of the class Arachnida rarely cause mortality in victims older than 6 years.¹⁸⁹ The venomous scorpions in the United States are *Centruroides exilicauda* and *Centruroides vittatus*. The most important is *C. exili cauda*, previously called *Centruroides sculpturatus* Ewing and *Centruroides gertschii* (bark scorpion; Table 118–6).⁸⁶

TABLE 118–6. Envenomation Gradation for *Centruroides exilicauda* (Bark Scorpion)

Grade	Signs and Symptoms
I	Site of envenomation Pain and/or paresthesias Positive tap test (severe pain increase with touch or percussion)
II	Grade I in addition to Pain and paresthesias remote from sting site (eg, paresthesias moving up an extremity, perioral “numbness”)
III	One of the following: Somatic skeletal neuromuscular dysfunction: jerking of extremity(ies), restlessness, severe involuntary shaking and jerking, which may be mistaken for seizures Cranial nerve dysfunction: blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculation, upper airway dysfunction, slurred speech
IV	Both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction

Pathophysiology

Components of scorpion venom are complex and species specific.^{109,181,189,190} Buthidae venom is thermostable and consists of phospholipase, acetylcholinesterase, hyaluronidase, serotonin, and neurotoxins. Four neurotoxins, designated toxins I to IV, have been isolated from *C. exilicauda*. Some of the toxins target excitable membranes,^{71,85,107,159,199} especially at the neuromuscular junction, by opening sodium channels. The results are repetitive depolarization of nerves in both sympathetic and parasympathetic nervous systems causing catecholamine and acetylcholine release, respectively, and associated cardiac hypoxia, and action at the juxtaglomerular apparatus, causing increased renin secretion.^{68,189} The clinical effects of *Tityus* scorpion sting are related to elevated concentrations of interleukin (IL)-1 β , IL-6, IL-8, IL-10, kinins,⁸⁹ and tumor necrosis factor (TNF)- α , which correlate with the severity of envenomation and hyperamylasemia.^{67,90}

Clinical Manifestations

Scorpion stings produce a local reaction consisting of intense local pain, erythema, tingling or burning, and occasionally discoloration and necrosis without tissue sloughing (Table 118–6). Depending on the scorpion species involved, systemic effects may occur, including autonomic storm consisting of cholinergic and adrenergic effects. Cardiotoxic effects include myocarditis, dysrhythmias, and myocardial infarction.^{71,85,107,159,199} Electrocardiographic (ECG) abnormalities may persist for several days and include sinus tachycardia, sinus bradycardia, bizarre broad notched biphasic T-wave changes with additional ST elevation or depression in the limb and precordial leads, appearance of tiny Q waves in the limb leads consistent with an acute myocardial infarction pattern, occasional electrical alternans, and prolonged QT interval.^{107,109} Other reported effects include pancreatitis, coagulation disorders, acute respiratory distress syndrome (ARDS), massive hemoptysis, cerebral infarctions in children, seizures, and a shock syndrome that may precede but usually follows the hypertensive phase.^{24,76,85,107,108,199,209}

In the United States, *C. exilicauda* stings produce local paresthesias and pain that can be accentuated by tapping over the envenomated area (tap test) without local skin evidence of envenomation.^{62,189} Symptoms begin immediately after envenomation, progress to maximum severity in 5 hours, and may persist for up to 30 hours.^{62,189} Autonomic findings include hypertension, tachycardia, diaphoresis, emesis, and bronchoconstriction. The somatic motor symptoms reported include ataxia, muscular fasciculations, restlessness, thrashing, and opsoclonus; rarely, children require respiratory support (Table 118–6).^{68,181}

Treatment

Because most envenomations do not produce severe effects, local wound care, including tetanus prophylaxis and pain management, usually is all that is warranted. In young children or patients who manifest severe toxicity, hospitalization may be required. Treatment emphasizes support of the airway, breathing, and circulation. Corticosteroids, antihistamines, and calcium have been administered without any known benefit.⁶⁷ Continuous IV midazolam infusion is often used for *C. exilicauda* scorpion envenomation until resolution of the abnormal motor activity and agitation occurs.⁹⁴

The severity of envenomation dictates the need to use antivenom, with antivenom indicated for grade III and grade IV envenomations. (Table 118–6).⁶⁷ When an equine-derived F(ab')₂ product called Alacramyn, developed in Mexico against the *Centruroides limpidus* venom, was administered to critically ill US children with neurotoxicity from scorpion stings, there was a rapid resolution of symptoms, decreased need for sedation, and reduced concentrations of circulating unbound venom.³⁴ This antivenom was subsequently approved in the United States in 2011 and called Anascorp (Bioclon, Mexico)⁷³ (Antidotes in Depth: A35). Because the neurotoxic syndrome occurs almost exclusively in children < 10 years of age, antivenom use is most likely to be considered in children. However, intractable pain in adults not responding to reasonable doses of opioids or other systemic effects that may pose a danger to the patient or a fetus should be considered potential indications for antivenom therapy.

Atropine has been used to reverse the excessive oral secretions in *C. exilicauda* scorpion envenomation, with some success in healthy children.²¹⁸ Routine use is not recommended and should be limited to species such as *Parabuthus transvaalicus* in southern Africa,²¹⁸ whose envenomations cause a prominent cholinergic crisis. Potentiation of the adrenergic effects causing cardiopulmonary toxicity is reported.²¹ Atropine use to reverse the effects of stings from scorpions from India, South America, the Middle East, and Asia is contraindicated because these scorpions cause an “autonomic storm” with transient cholinergic stimulation followed by sustained adrenergic hyperactivity.^{20,218}

TICKS

In 1912, Todd described a progressive ascending flaccid paralysis after bites from ticks.²²⁹ Three families of ticks are recognized: (1) Ixodidae (hard ticks), (2) Argasidae (soft ticks), and (3) Nuttalliellidae (a group that has characteristics of both hard and soft ticks and not thought to be parasitic compared to ixodids and argasids). The terms hard and soft refer to a dorsal scutum or “plate” that is present in the Ixodidae but absent in the Argasidae. Both types are characteristically soft and leathery, and both have clinical importance. Ixodidae females are capable of enormous expansion up to 50 times their weight in fluid and blood.⁹³ The paralytic syndrome can be induced following envenomation during the larva, nymph, and adult stages and is related to the tick obtaining a blood meal. The following discussion focuses only on tick paralysis (TP) or tick toxicosis and not on any of the infectious diseases associated with tick bites. Most of the major tick-borne diseases in North America are transmitted by Ixodid ticks except for relapsing fever, which is spread by the soft tick of the genus *Ornithodoros* or *Pediculus humanus* (human louse).

In North America, *Dermacentor andersoni* (Rocky Mountain wood tick) and *Dermacentor variabilis* (American dog tick), and *Amblyomma americanum* (Lone Star tick) are the most commonly implicated causes of TP.^{99,229} Typically, tick toxicosis occurs in the Southeast, Rocky Mountain, and Pacific Northwest regions of the United States, but cases are also reported in the Northeast.⁷² In Australia, the *Ixodes holocyclus* or Australian marsupial tick is the most common

offender.^{99,229} I. holocyclus also seems to be the most potent of the world's paralyzing ticks and has been known to paralyze dogs, cats, sheep, mice, foals, pigs, chickens, and humans.¹⁵⁴

Pathophysiology

Venom secreted from the salivary glands during the blood meal is absorbed by the host and systemically distributed. To allow successful feeding over several days, ticks need to overcome the host's hemostatic, inflammatory, and immune mechanisms by producing anticoagulants, fibrinolytic enzymes, antiplatelet and vasodilator substances.^{140,188} The saliva also contains some cement to anchor the tick to the host, the hypostome of the I. holocyclus reaches up to 980 microns into the host's skin and does not need cement support.⁶ Paralysis results from the neurotoxin "ixobotoxin,"¹⁶⁷ which inhibits the release of acetylcholine at the neuromuscular junction and autonomic ganglia, very similar to botulinum toxin.^{102,167} Both botulinum toxin and ixobotoxin demonstrate temperature dependence in rat models and show increased muscular twitching activity as the temperature is reduced.^{64,154} The salivary toxin of I. holocyclus directly affects vascular and cardiac potassium channels by blockade, and this action differed from the respiratory distress caused by progressive muscle paralysis.¹¹ Cardiovascular function was decreased in dogs with TP. The dogs developed acute left-sided congestive heart failure and prolonged QT intervals were noted.⁵¹

Clinical Manifestations

Usually the tick must remain on the person for 5 to 6 days in order to result in systemic effects. Several days must pass before tick salivary glands begin to secrete significant quantities of toxin. Once secreted, the toxin does not act immediately and may undergo binding and internalization, in a similar sequence to botulinum toxin.^{18,64,136} Ticks typically attach to the scalp but can be found on any part of the body, including the ear canals and anus. Children, particularly girls, and adult men in tick-infested areas are predominantly affected. One large series of 305 cases in Canada reported that 21% were adults older than 16 years.²⁰⁴ Among the children, 67% were girls; in adults, 83% were male. The distribution was attributed to the difficulty of detecting ticks in long hair and the possible greater exposure of adult men to tick-infested environments. Children may appear listless, weak, ataxic, and irritable for several days before they develop an ascending paralysis that begins in the lower limbs. Fever usually is absent. Other manifestations include sensory symptoms such as paresthesias, numbness, and mild diarrhea. These symptoms are followed by absent or decreased deep-tendon reflexes and an ascending generalized weakness that can progress to bulbar structures involving speech, swallowing, and facial expression within 24 to 48 hours, as well as fixed, dilated pupils and disturbances of extraocular movements.^{102,204} Other atypical presentations are reported and include the following: a child presenting with double vision and being unable to see before the neuromuscular changes occurred, and a healthy elderly man presenting with unilateral weakness and numbness in the left arm for 2 days. Both patients fully recovered after the removal of the tick.⁷² If the tick is not removed, respiratory weakness can lead to hypoventilation, lethargy, coma, and death. Unlike the Dermacentor spp of North America, removal of the I. holocyclus tick does not result in dramatic improvement for several days to weeks. The maximal weakness may not be reached until 48 hours after the tick has been removed or drops off.¹⁰² It is imperative to closely observe patients for possible deterioration. A recent 60-year meta-analysis of TP in the United States reviewed 50 well-documented cases from 1946 to 2006 supporting the above findings.⁷⁸ The demographics were analyzed and the following remained the same: (1) TP is highly predictable regional disease found in the US Pacific Northwest (WA), the West (CA, CO), and the Southeast (GA, MS, NC, SC, VA), and very few cases occurred outside those areas; (2) TP remains a highly predictable seasonal disease occurring during the spring to summer seasons; (3) TP remains more common in females of all ages (80% female/male 4.9:1); (4) Tick attachment sites on the head and scalp continued to predominate over all other attachment sites, representing 48% of the reported attachment sites, 20% occur behind the ear; (5) The Rocky Mountain wood tick (D. Andersoni) was the only TP vector in the western United States (CA, WA, CO) when reported, and D. variabilis, the American dog tick, was the only TP vector from the southeastern United States (GA, NC) when reported.

The differential diagnosis is extensive and includes Guillain-Barré syndrome (GBS), the Miller-Fisher variant of Guillain-Barré, poliomyelitis, botulism, transverse myelitis, myasthenia gravis, periodic paralysis, elapid snakebites, marine neurotoxin poisoning, acute cerebellar ataxia, and spinal cord lesions. The cerebrospinal fluid remains normal, and the rate of progression is rapid, unlike GBS and poliomyelitis.^{78,84,201} The edrophonium test is negative. Nerve conduction studies in patients with TP may resemble those of patients with early stages of GBS: findings in both conditions include prolonged latency of the distal motor nerves, diminished nerve conduction velocity, and reduction in the amplitudes of muscle and sensory-nerve action potentials.⁸⁴ With GBS, there is a prolongation of the F wave, however, which does not occur with TP, reflecting the more proximal demyelination of the nerve root.¹⁰⁴ The other causes for acute ascending flaccid paralysis should be eliminated by a complete history, including environmental exposure, hobbies, workplace, travel, ingestions, obtaining appropriate laboratory testing, psychiatric evaluations if needed, and of course a thorough physical examination.

Treatment

Other than removal of the entire tick, which is curative, treatment is entirely supportive. Proper removal of the tick is very important, otherwise infection or incomplete tick removal may occur. The tick should be grasped as close to the skin surface as possible with blunt curved forceps, tweezers, or gloved hands. Steady pressure without crushing the body should be used; otherwise, expressed fluid may infect the patient and lead to inoculating the patient with a higher dose of toxin or infectious agent. After tick removal, the site should be disinfected. Traditional methods of tick removal using petroleum jelly, topical lidocaine, fingernail polish, isopropyl alcohol, or a hot match head are ineffective and may induce the tick to salivate or regurgitate into the wound.¹⁷⁰ It should be remembered that the very same vectors responsible for tick toxicosis can also cause infectious illnesses such as babesiosis, Rocky Mountain spotted fever, anaplasmosis, tularemia, Colorado tick fever, tick-borne relapsing fever, and Lyme disease. Since *I. holocyclus* of Australia is considerably more toxic and patients are more likely to deteriorate before they improve, close observation is required for several days until improvement is certain.⁸⁴ A hyperimmune serum prepared from dogs is the usual treatment for paralyzed animals, but it has been used sparingly in severely ill humans because of the risk of acute reactions and serum sickness.⁸⁴

HYMENOPTERA: BEES, WASPS, HORNETS, YELLOW JACKETS, AND ANTS

Within the order Hymenoptera are three families of clinical significance: Apidae (honeybees and bumblebees), Vespidae (yellowjackets, hornets, and wasps), and Formicidae (ants, specifically fire ants). These insects (Fig. 118–6) are of great medical importance because their stings are the most commonly reported and can cause acute toxic and fatal allergic reactions. In the 1960s and 1970s, an estimated 40 deaths per year were attributed to anaphylaxis secondary to hymenoptera stings in the United States.^{17,208} However, from 2008 to 2011 there have been only two deaths related to envenomations from bees, wasps, and hornets reported to the National Data Poisons System, probably due to increased public awareness of allergic reactions and easier access to medical care.^{37,38,39,41}

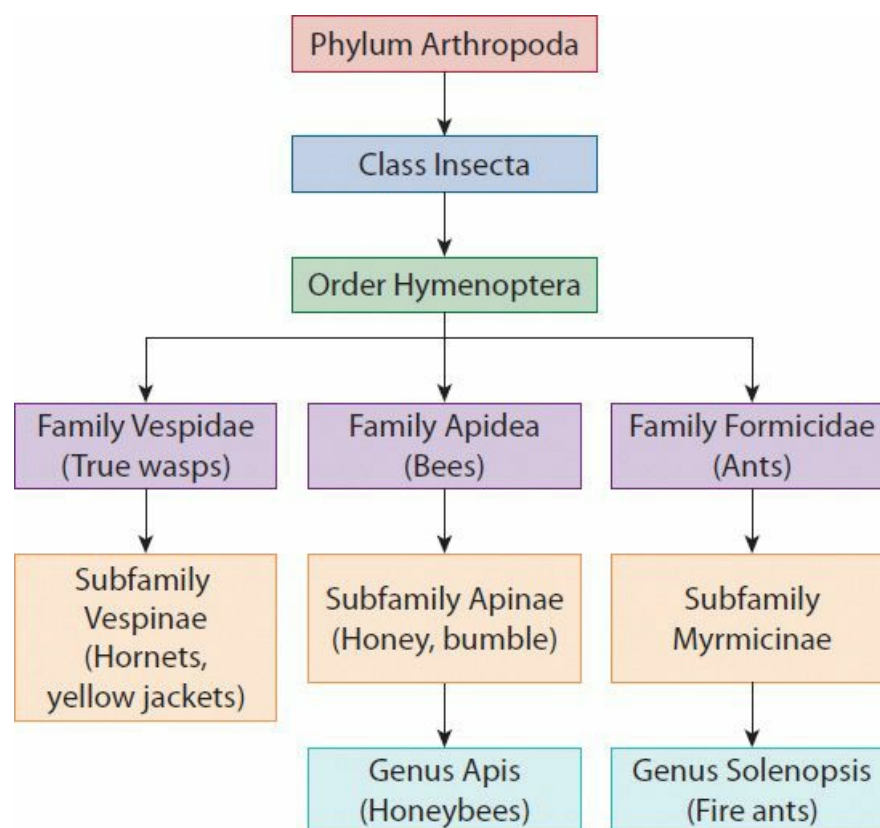

FIGURE 118-6 Taxonomy of the order Hymenoptera.

Apis and *Bombus* species (honeybees and bumblebees) generally build nests away from humans and are passive unless disturbed, but nests of both the honeybees and bumblebees have been found in walls and rodent burrows near homes. Honeybee workers can only sting once because their stinger is a modified ovipositor that resides in the abdomen and its shaft is barbed and has a venom sac attached. Once the stinger embeds into the skin, the stinger disembowels the bee. Bumblebees, however, can sting multiple times. Vespids, on the other hand, are more aggressive and build nests in human living areas, such as in trees and under awnings; yellow jackets inhabit shrubs, trees, and the ground. They, too, are able to sting multiple times.⁹⁶ The introduction of the Africanized honeybee in Brazil (because originally they were thought to be a

more efficient honey producer) has caused significant economic and health issues. The bees have migrated toward the southern border of the United States and pose a greater threat to humans. Africanized honeybees are characterized by large populations, can make nonstop flights of at least 20 km, and have a tendency toward mass attack with little provocation.¹⁶⁴

Pathophysiology

Several allergens (Table 118–7) and pharmacologically active compounds are found in honeybee venom. The three major venom proteins are found in the honeybee: melittin, phospholipase A₂, and hyaluronidase.¹⁴⁹ Other proteins include apamin, acid phosphatase, and other unidentified proteins. Phospholipase A₂ is the major antigen/allergen in bee venom.³²

TABLE 118–7. Composition of Hymenoptera Venom

<i>Vespid (Wasps, Hornets, Yellow Jackets)</i>	<i>Apids (Honeybees)</i>	<i>Formicids (Fire Ants)</i>
Biogenic amines (diverse)	Biogenic amines (diverse)	Biogenic amines (diverse)
Phospholipase A, phospholipase B	Phospholipase A, phospholipase B (?)	Phospholipase A
Hyaluronidase	Hyaluronidase	Hyaluronidase
Acid phosphatase	Acid phosphatase	Piperidines
Mast cell degranulating peptide	Minimine	
Kinin	Mellitin	
	Apamin	
	Mast cell degranulating peptide	

Melittin is the principal component of honeybee venom. It acts as a detergent to disrupt the cell membrane and liberate potassium and biogenic amines.¹⁴ Histamine release by bee venom appears to be largely mediated by mast cell degranulation peptide. Apamin is a neurotoxin that acts on the spinal cord. Apamin binds to the Ca⁺²-triggered K⁺ channel and depresses delayed hyperpolarization to cause its toxicity, which is seen in the mouse model as uncoordinated movements leading to spasms, jerks, and convulsions of a spinal origin.¹¹² Adolapin inhibits prostaglandin synthase and has antiinflammatory properties that may account for its use in arthritic therapy.²⁰⁶ Phospholipase A₂ and hyaluronidase are the chief enzymes in bee venom.

The three major proteins in vespid venoms serve as allergens and are accompanied by a wide array of vasoactive peptides and amines.¹⁴⁹ The intense pain following vespid stings is largely caused by serotonin, acetylcholine, and wasp kinins. Antigen 5 is the major allergen in vespid venom.¹⁶⁵ Its biologic function is unknown. Mastoparans have action similar to mast cell degranulation peptide, but weaker.¹⁴ Phospholipase A₂ may be responsible for inducing coagulation abnormalities.¹⁷⁵

Clinical Manifestations

Normally, the honeybee sting is manifested as immediate pain, a wheal-and-flare reaction, and localized edema without a systemic reaction. Vomiting, diarrhea, and syncope can occur with a higher dose of venom resulting from multiple stings.³⁵ Rarely, a sting in the oropharynx produces airway compromise.²⁰⁸

Toxic reactions occur with multiple stings (more than 500 stings are described as possibly fatal and occur with Africanized honeybees)⁹⁶ and include gastrointestinal (GI) symptoms, headache, fever, syncope and, rarely, rhabdomyolysis, acute kidney injury, and seizures.³⁵ Other rare complications include idiopathic intracranial hypertension,²²⁶ cerebral infarction, and ischemic optic neuropathy²⁰³ and Parkinsonism¹⁴⁸ and are thought to occur because of the proximity of the sting near the head and neck. Bronchospasm and urticaria are typically absent.

This type of toxic reaction is different from the hypersensitivity reactions or anaphylactic reactions because it is not an IgE-mediated response, but rather a direct effect from the venom itself. Hypersensitivity reactions, including anaphylaxis, occur from Hymenoptera stings. These reactions are IgE mediated. The IgE antibodies attach to tissue mast cells and basophils in individuals who have been previously sensitized to the venom. These cells are activated, allowing for progression of the cascade reaction of increased vasoactive substances, such as leukotrienes, eosinophil chemotactic factor-A, and histamine. An anaphylactic reaction is not dependent on the number of stings. Patients who are allergic to hymenoptera venom develop a wheal-and-flare reaction at the site of the inoculum. The shorter the interval between the

sting and symptom onset, the more likely the reaction will be severe. Fatalities can occur within several minutes; even initially mild symptoms may be followed by a fulminant course. Generalized urticaria, throat and chest tightness, stridor, fever, chills, and cardiovascular collapse can ensue.

Treatment

Application of ice at the site usually is sufficient to halt discomfort. Stingers from honeybees should be removed by scraping with a credit card or scalpel, as opposed to pulling, which may release additional retained venom. Since the stinger in other bee species typically stays within the insect, this removal technique would not be necessary if other bee species are involved. Therapy is aimed at supportive care that includes standard therapy for anaphylaxis with epinephrine, diphenhydramine, and corticosteroids.

FIRE ANTS

There are native fire ants in the United States, but the imported fire ants *Solenopsis invicta* and *Solenopsis richteri* are significant pests that have no natural enemies. They are native to Brazil, Paraguay, Uruguay, and Argentina but were introduced into Alabama in the 1930s. They have spread rapidly throughout the southern United States, damaging crops, reducing biologic diversity, and inflicting severe stings to humans.²²⁴ *S. invicta*, the most aggressive species, now infests 13 southern states and has been introduced into Australia.^{210,213} Allergic reactions to ant stings were limited to the jumper ant (*Myrmecia pilosula*, other *Myrmecia* spp) and the greenhead ant (*Rhytidoponera metallica*; *Odontomachus*, *Cerapachys*, and *Brachyponera* spp) in Australia until February 2001, when the imported red fire ant was identified at two sites in Brisbane.²¹⁰ The mode of introduction is unknown but may have originated from the transport of infested cargo. Fire ants range from 2 to 6 mm in size. They live in grassy areas, garden sites, and near sources of water. The nests are largely subterranean and have large, conspicuous, dome-shaped above-ground mounds (up to 45 cm above the ground), with many openings for traffic. The mounds can contain 80,000 to 250,000 workers and one or more queens that live for 2 to 6 years and produce 1500 eggs daily.²³⁵ Fire ants are named for the burning pain inflicted after exposure, and necrosis can result at the site. The imported fire ant attacks with little warning. By firmly grasping the skin with their mandibles, both the fire ant and the jumper ant can repeatedly inject venom from a retractile stinger at the end of the abdomen. Pivoting at the head, the fire ant injects an average of seven or eight stings in a circular pattern.²¹³

Pathophysiology

The venom inhibits sodium and potassium adenosine triphosphatases, reduces mitochondrial respiration, uncouples oxidative phosphorylation, adversely affects neutrophil and platelet function, inhibits nitric oxide synthetase, and perhaps activates coagulation.^{133,135} Unlike the venoms of wasps, bees, and hornets that contain mostly aqueous-containing proteins, the imported fire ant venom is 95% alkaloid, with a small aqueous fraction that contains soluble proteins.¹⁵² Of the alkaloids, 99% is a 2,6-disubstituted piperidine that has hemolytic, antibacterial, insecticidal, and cytotoxic properties.⁷⁴ There is also some in vivo evidence that the Solenopsin alkaloids can inhibit nitric oxide synthetase activity and has direct cardiotoxic, convulsant, and respiratory depressant activities.^{123,243} These alkaloids do not cause allergic reactions, but they produce a pustule and pain. The aqueous portion of the venom contains the allergenic activity of fire ant venom, Sol i I to IV.^{116,213} The proteins identified in the venom include a phospholipase, a hyaluronidase, and the enzyme N-acetyl- β -glucosaminidase.^{75,213}

Clinical Manifestations

In the United States, residents of health care facilities who are immobile or cognitively impaired are at risk for fire ant attacks, especially when the facility lacks pest control techniques for fire ants.⁷⁵ Three categories are suggested based on the reactions to the imported fire ant: local, large local, and systemic.²¹³ Local reactions occur in nonallergic individuals. Large local reactions are defined as painful, pruritic swelling at least 5 cm in diameter and contiguous with the sting site. Systemic reactions involve signs and symptoms remote from the sting site. The sting initially forms a wheal that is described as a burning itch at the site, followed by the development of sterile pustules. In 24 hours, the pustules umbilicate on an erythematous base. Pustules may last 1 to 2 weeks.⁹⁶ Late cutaneous allergic reactions can occur in some persons who experience indurated pruritic lumps at the site of subsequent stings.⁷⁴ Large reactions may lead to tissue edema sufficient to compromise blood flow to an extremity. Anaphylaxis occurs in 0.6% to 6% of persons who have been stung.²¹³ Often, healing occurs with scarring in 10 to 14 days.

The majority of individuals who die after fire ant attacks succumbed to heart failure.⁷⁵ These individuals came from nursing homes primarily; however, the solenopsins were found to strongly inhibit myocardial contractility which might explain the heart failure that occurred after massive envenomations.^{75,123}

Diagnosis

Clinical clues such as pustule development at the sting site after 24 hours, species identification, and history may help to identify fire ant exposure. No laboratory assays to determine exposure are available. Fire ant allergy can be determined by correlating the clinical manifestation of fire ant sting reactions with imported fire ant–specific IgE determined by skin testing or radioallergosorbent test.

Treatment

Local reactions require cold compresses and cleansing with soap and water. Some authors recommend topical or injected lidocaine with or without 1:100,000 epinephrine, and topical vinegar and salt mixtures to decrease pain at the site of the bite and sting.^{43,120,157,193}

Large local reactions can be treated with oral corticosteroids, antihistamines, and analgesics. Secondary infections should be treated with antibiotics. Systemic reactions should be treated with subcutaneous or intravenous epinephrine

BUTTERFLIES, MOTHS, AND CATERPILLARS

Butterflies and moths are insects of the order Lepidoptera. Several moth and butterfly families have species whose caterpillars are clinically important, that is, they contain spines or urticating hairs that secrete a poison that is irritating to humans on contact. Lepidopterism is a general term that describes the systemic adverse effects such as generalized urticaria, headache, pharyngitis, conjunctivitis, nausea, vomiting, bronchospasm, wheezing, and dyspnea that occur when humans are exposed to moths and butterflies.¹⁶⁶ Erucism is the term used when a cutaneous dermatitis results from contact with urticating caterpillars, the larval forms of the insect order Lepidoptera (moths and butterflies).⁷⁹ Caterpillar species from about 12 families of moths and rarely butterflies worldwide can inflict serious human injuries, including urticarial dermatitis, allergic reactions, consumptive coagulopathy, acute kidney injury, intracerebral hemorrhage, arthritis, joint deformity, and even altered mental status, ataxia, and dysarthria.^{79,122}

Caterpillar, which means hairy cat in Latin, is the larval stage for moths and butterflies. In the United States, several significant stinging caterpillars are of note. Often the puss caterpillar (*Megalopyge opercularis*) is considered one of the most important and toxic of the caterpillars in the United States because of the frequency with which reactions have been reported, especially in Texas.²¹⁵ Other names for the puss caterpillar are woolly/hairy worm, wooly slug, opossum bug, tree asp, Italian asp, and “el perrito” in Spanish.²¹⁵ The caterpillars look furry and are covered in silky tan to brownish hairs that hide short spines containing an urticarial toxin. The spines are yellowish with black tips, and the hairs vary in color ranging from pale yellow and gray to brown.²⁹ Other significant stinging caterpillars in the United States are the flannel moth caterpillar (*Megalopyge crispata*), the Io moth (*Automeris io*), the saddleback caterpillar (*Sibine stimolata*), and the hickory tussock caterpillar (*Lophocampa caryae*).¹⁴⁷ In South America, especially Brazil, *Lonomia obliqua* caterpillars are notorious for causing severe pain and a hemorrhagic syndrome.^{52,69} In Australia, several caterpillars are of medical importance: mistletoe brown tail moth (*Euproctis edwardsi*), processionary caterpillars (*Ochrogaster lunifer*), cup moths (*Doratifera* spp), and the white-stemmed gum moth (*Chelepteryx collesi*).¹³ Pine processionary caterpillars (*Thaumetopoea pityocampa*) are the most important defoliator of pine forests in the Mediterranean and central European countries, with significant consequential economic and occupational repercussions for workers who frequent these pine forests.²³⁰ In Nigeria, the *Anaphe venata* caterpillar is an important resource for protein that can cause thiamine deficiency syndrome similar to dry beriberi. Finally, the dendrolimus caterpillars of China and the *Preolis semirufa* caterpillars in Brazil cause significant joint disease.

Pathophysiology

The pathophysiology of dendrolimiasis is not understood, but the tegument-produced venom contains formaldehyde and several uncharacterized histamine analogs with a tropism for receptors in bone, joints, and cartilage and during the acute phase may result from IgE-mediated allergy to foreign proteins, and the chronic bone and joint disease may be autoimmune mediated.¹²⁵ The composition of the venom varies according to the different caterpillar species. Some toxins contain proteins that cause histamine release, such as thaumetopoein isolated from *T. pityocampa* or pine processionary caterpillar.^{230,231} Another protein isolated from the *L. obliqua* caterpillar causes coagulopathy. It is called lonomin V and is a proteolytic enzyme, which is isolated in the hairs, spines, and hemolymph of the *L. achelous*.¹¹¹ Its mechanism of action is not fully known, but it somehow activates factors X and II, and there is some evidence that collagen degradation might be responsible for platelet inhibition.^{80,110,138} The venom and hair structure of *Lagoa crispata*, which has often been confused with the southern Texas puss caterpillar, has been characterized.¹⁴⁷ The venom is stored at the base of the hollow setae (spines) where the poison sac and nervous tissue are located. Upon contact with these spines, the toxin is released. The toxin may be a protein or a substance that conjugates with proteins.⁸⁷ The varying differences of caterpillar venom and their

clinical effects emphasize the importance of positive identification of caterpillars.

Clinical Manifestations

The pathophysiologic effects of venomous caterpillar exposures can be classified into seven distinct clinical syndromes to guide clinicians in making earlier, more species-specific diagnoses to direct therapies, including: (1) erucism, (2) lepidopterism, (3) dendrolimiasis, (4) ophthalmia nodosa, (5) consumptive coagulopathy with secondary fibrinolysis,⁷⁹ (6) seasonal ataxia, and (7) paramorse.¹²² Erucism is the preferred term for caterpillar dermatitis caused by contact with caterpillar urticating hairs, spines, or toxic hemolymph. Lepidopterism is a systemic illness caused by a constellation of adverse effects resulting from direct or aerosol contact with caterpillar, cocoon, or moth urticating hairs, spines or body fluids and is characterized by generalized urticaria, headache, conjunctivitis, pharyngitis, nausea, vomiting, bronchospasm, wheezing, and, rarely, dyspnea. Dendrolimiasis is a chronic form of lepidopterism caused by direct contact with urticating hairs, spines, or hemolymph of living or dead central Asian pine-tree lappet moth caterpillars or their cocoons and is characterized by urticating maculopapular dermatitis, migratory inflammatory polyarthritis, migratory inflammatory polychondritis, chronic osteoarthritis, and, rarely, acute scleritis.¹²⁵ Ophthalmia nodosa is a chronic ocular condition characterized by initial conjunctivitis with subsequent panuveitis caused by corneal penetration and subsequent intraocular migration of urticating hairs from lymantriid caterpillars and moths and therapsid spiders (tarantulas).

The South American *Lonomia saturniid* moth caterpillars range from Venezuela to northern Argentina and pose a threat in Brazil due to the high fatality rates from venom-induced consumptive coagulopathy, intracerebral hemorrhage, and acute renal failure, possibly due to a combination of venom nephrotoxicity and microcirculatory fibrin deposition.⁴⁶ The hemorrhagic syndrome can present as a disseminating intravascular coagulopathy and as a secondary fibrinolysis with skin, mucosal, and visceral bleeding, acute kidney injury, and intracerebral hemorrhage.^{52,138}

Seasonal ataxia is a syndrome of unsteady gait and dysarthria, which occurs after the ingestion of the caterpillar of *Anaphe venata*. This occurs in areas of Nigeria where they are a source of protein.^{3,4} Ingestion of the roasted larvae causes nausea and vomiting and progresses to dizziness, ataxia, and unsteady gait in more than 90% of victims. These symptoms may take weeks to months for resolution. Dysarthria and impaired consciousness have also been reported. The pathogenesis is related to thiamine deficiency induced by the caterpillars.

Paramorse is similar to dendrolimiasis with pruritic or painful dermatitis associated with arthritis and joint deformity, arising from contact with the caterpillar of *Premolis semirufa*, which are found in the Brazilian Amazon rain forests. Rubber tree plantation workers are particularly at risk even when wearing protective gloves.^{66,77}

The clinical effects of caterpillar exposure can generally be separated into two types—stinging reaction and pruritic reaction—although overlap may occur. Stinging caterpillars, such as *M. opercularis*, envenomate by contact with their hollow spines containing venom. The reaction is characterized as a painful, burning sensation with local effects and, less commonly, systemic effects. The area may become erythematous and swollen, and papules and vesicles may appear. The classic gridlike pattern develops within 2 to 3 hours of contact. Reported symptoms include nausea, vomiting, fever, headache, restlessness, tachycardia, hypotension, urticaria, seizures, and even radiating lymphadenitis and regional adenopathy.¹⁷⁷ Pruritic reactions occur upon exposure to the itchy caterpillars that have nonvenomous urticating hairs, which can produce a mechanical irritation, allergic reaction, or a granulomatous reaction from the chronic presence of the hairs. Several species that cause allergic reactions are the white-stemmed moth (*C. collesi*), Douglas fir tussock moth (*Orgyia pseudotsugata*), and gypsy moth caterpillar (*Lymantria dispar*).¹⁶⁶ Caterpillar hairs can cause ocular trauma, otherwise known as ophthalmia nodosa.²¹² The range of ocular pathology depends on the penetration factor and the effect of the released urticating toxins.⁵⁰ The ocular spectrum has been classified into five types.⁵⁰

Type 1: Brief exposure time of 15 minutes. Symptoms of chemosis, inflammation, epiphora, and foreign body sensation may last for weeks.

Type 2: Chronic mechanical keratoconjunctivitis (hairs in bulbar/palpebral conjunctivitis). Foreign body sensation is relieved by removal of hairs. Corneal abrasions may be present.

Type 3: Gray-yellow nodules or asymptomatic granulomas.

Type 4: Severe iritis with or without iritis nodules; hairs are in the anterior chamber and possible intralenticular foreign body.

Type 5: Vitreoretinal involvement. Hairs may enter through the anterior chamber or iris lens or by transscleral migration. May cause vitreitis, cystoid macular edema, papillitis, or endophthalmitis.

Treatment

Management for most dermal caterpillar envenomations is entirely supportive and includes washing the area with soap and water; “no touch” drying of the sting site with a hair dryer; gentle stripping of the bite site with cellophane or adhesive duct

tape; and application of ice packs with cooling enhanced by initial topical swabbing with isopropyl alcohol. Rings should be removed in anticipation for potential swelling of the extremity, and tetanus prophylaxis should be updated accordingly.⁷⁹

Treatment of ocular lesions depends upon the exposure classification and should be managed by the ophthalmologist. Most patients can be classified as type 1 or 2. Irrigation with 0.9% sodium chloride solution should be followed by meticulous removal of setae, followed by topical steroids and antibiotics. Type 3 requires surgical excision of the nodules. Type 4 requires topical steroids with or without iridectomy for nodules or operative removal of setae. Type 5 requires local treatment with or without systemic steroids. Resistant cases may require vitrectomy with removal of setae.

Opioids may be necessary, if minor analgesics do not provide relief. If muscle cramps develop, benzodiazepines should be administered. One study recommended the use of 10 mL 10% calcium gluconate administered IV, which provided pain relief.¹⁶⁰ Topical corticosteroids can be used to decrease local inflammation. Antihistamines such as diphenhydramine (25–50 mg for adults and 1 mg/kg, maximum 50 mg, in children) can be used to relieve pruritus and urticaria.^{160,177} Nebulized β -agonists and epinephrine administered subcutaneously may be required for more severe respiratory symptoms and anaphylactoid/anaphylactic-type reactions. Dendrolimiasis treatment consists of mostly supportive care with early surgical intervention recommended to excise draining sinus tracts and infected cartilage and to prevent permanent bone and joint deformities.¹²⁵ For hemorrhagic syndrome resulting from exposure to *L. obliqua* caterpillar, besides restoration of clotting factors, platelet, and cryoprecipitate infusions, an antidote called the antilonomic serum (SALon) is available and is used for treatment of the hemorrhagic syndrome in Brazil.⁶⁹ It is important to involve an experienced hematologist for suspected *Lonomia* envenomation and very important to distinguish *Lonomia obliqua* from *Lonomia achelous* because the cryoprecipitate, purified fibrinogen, and antifibrinolytic drugs, such as aprotinin and ϵ -aminocaproic acid, have been successfully used in *Lonomia achelous* but may exacerbate the hemorrhagic symptoms in *Lonomia obliqua* with fatal consequences.^{59,98} Patients exposed to either species should neither receive whole blood nor fresh plasma or they may worsen clinical symptoms. Treatment for the seasonal ataxia includes supportive care with the administration of thiamine 100 mg orally every 8 hours, which found reversal of symptoms within 48 hours without long term sequelae in a double blinded placebo controlled trial.²

BLISTER BEETLES

Blister beetles are plant-eating insects that exude a blistering agent for protection. They can be found in the eastern United States, southern Europe, Africa, and Asia. Most are from the order Coleoptera, family Meloidae. *Epicauta vittata* is the most common of more than 200 blister beetles identified in the United States.¹³⁷ When the beetles sense danger, they exude cantharidin by filling their breathing tubes with air, closing their breathing pores, and building up body fluid pressure until fluid is pushed out through one or more leg joints.⁹⁶ Cantharidin is a potent blistering agent found throughout all 10 stages of life of the blister beetle.⁵⁴ Cantharidin is produced only by the male blister beetle and is stored until mating. In the wild, the female repeatedly acquires cantharidin as copulatory gifts from her mates. However, the female blister beetle loses most of her reserves as she matures.⁵⁴ Cantharidin, also known popularly as Spanish fly, takes its name from the Mediterranean beetle *Cantharis vesicatoria*. It has been ingested as a sexual stimulant for millennia. The aphrodisiac properties are related to the ability of cantharidin to cause vascular engorgement and inflammation of the genitourinary tract upon elimination, hence the reports of priapism and pelvic organ engorgement.²²⁸ Cantharidin was once used for treatment of bladder and kidney infections, stones, stranguria (bladder spasm), and various venereal diseases.¹³⁷ In the last century, cantharidin was commonly used for treatment of pleurisy, pneumonia, arthritis, neuralgias, and various dermatitides. A topical 1% commercial preparation can be used for removal of warts and molluscum contagiosum.^{65,205} Cantharidin poisoning is reported by cutaneous exposure,⁴² unintentional inoculation,¹⁸⁰ and inadvertent ingestion of the beetle itself.²²⁵ There is one case report of a child being treated for molluscum contagiosum with cantharidin preparation that included podophyllin and salicylic acid, also called Canthacur PS or Canthacur Plus.²⁰⁵ The child developed varicelliform vesicular dermatitis in the distribution of the application of petrolatum. It is thought that the petrolatum used by the parents to moisturize her skin spread the lipophillic cantharidin preparation to the nearby areas causing the blistering reaction. Canthacur PS should not be used for molluscum contagiosum but is reserved for verrucae vulgaris on acral areas. Canthacur or Cantharone contains plain cantharidin and can be used for the treatment of molluscum contagiosum. Fewer than 30 cases of Spanish fly poisoning have been reported since 1900.¹³⁷

Pathophysiology

Cantharidin is a natural, defensive, highly toxic terpenoid (lethal dose for humans 0.5 mg/kg) produced by blister beetles and shares a structural similarity with the herbicide Endothall.¹⁴⁹ Endothall causes corrosive effects to the GI tract; cardiomyopathy and vascular permeability lead to shock. A single case report of lethal poisoning with 7 to 8 g of endothall has been reported, and the healthy young male died of hemorrhage of the GI tract and lung, which is clinically similar to the cantharidin exposures. Although the mechanism of action has not been elucidated, one mechanism based on an in vitro study

suggests that cantharidin inhibits the activity of protein phosphatases type 1 and 2A. This inhibition alters endothelial permeability by enhancing the phosphorylation state of endothelial regulatory proteins and results in elevated albumin flux and dysfunction of the barrier.¹⁴³ Enhanced permeability of albumin may be responsible for the systemic effects of cantharidin, which lead to diffuse injury of the vascular endothelium and resultant blistering, hemorrhage, and inflammation.

Clinical Manifestations

The clinical effects can mostly be attributed to the irritative effects on the exposed organ systems. The secretions of cantharidin from the beetle's leg joints cause an urticarial dermatitis that is manifested several hours later by burns, blisters, or vesiculobullae.⁴² Symptoms may be immediate or delayed over several hours. In addition to the local effects, cantharidin can be absorbed through the lipid bilayer of the epidermis and cause systemic toxicity, with diaphoresis, tachycardia, hematuria, and oliguria from extensive dermal exposure.²²⁸ If the periorbital region is contaminated, edema and blistering can evolve. Ocular findings from direct contact with the beetle or hand contamination include decreased vision, pain, lacrimation, corneal ulcerations, filamentary keratitis, and anterior uveitis.¹⁸⁰ Most human exposures involve inadvertent contact with the beetle or its secretions, resulting in dermatitis, keratoconjunctivitis, and periorbital edema secondary to hand-eye involvement, also called the Nairobi eye.¹⁸⁰

When cantharidin is ingested, severe GI disturbances and hematuria can occur. Initial patient complaints may include burning of the oropharynx, dysphagia, abdominal cramping, vomiting, hematemesis followed by lower GI tract hematochezia, and tenesmus. An inadvertent blister beetle ingestion by a child who thought it was the edible *Eulepida mashona* or white grub resulted in hematuria and abdominal cramping.²²⁵ Genitourinary effects include dysuria, urinary frequency, hematuria, proteinuria, and renal impairment. Most symptoms resolved over several weeks. However, death from renal failure with acute tubular necrosis is reported.²²⁸

Diagnostic Testing

Cantharidin toxicosis has been identified for equine and ruminant exposures by screening urine and gastric contents with high-performance liquid chromatography and gas chromatography-mass spectrometry.^{184,185} This method has not been used in clinical practice.

Treatment

Treatment is largely supportive. Wound care and tetanus status should be assessed. For keratoconjunctivitis, an ophthalmologist should be consulted early in the clinical course and the patient treated with topical corticosteroids (prednisolone 0.125%), mydriatics (cyclopentolate 1%), and antibiotics (ciprofloxacin 0.3%).

SUMMARY

- Health care providers should have an extensive knowledge regarding the identification of arthropods and their bites and stings so they can provide optimal care to their patients.
- Black widow: Lactrodectism is a painful neurotoxic condition best known for causing intense muscle spasms associated with short term autonomic and central nervous system dysfunction.
- Brown recluse: Loxoscelism is manifested by necrotic tissue loss, which is less often accompanied by systemic reactions such as hemolysis, coagulopathy, renal failure, and death.
- Scorpions: Envenomation releases a neurotoxin that opens the sodium channels to cause an array of effects the envenomation leads to local as well as systemic effects that activate the sympathetic and parasympathetic branches of the nervous system leading to intense pain, edema, and erythema as well as severe hypertension and tachy- or brady-dysrhythmias.
- Ticks: Ticks are vectors that are commonly known to transmit disease but in the setting of envenomations, one must remember tick toxicosis in the differential as a cause of progressive ascending flaccid paralysis that can be fatal if the tick is not removed.
- Caterpillars: Lepidopterism is another cause of common human envenomations that typically cause dermal and ocular symptoms.

A34 ANTIDOTES IN DEPTH

Antivenom: Spider

Michael A. Darracq and Richard F. Clark

INTRODUCTION

The terms “antivenom” and “antivenin” often are used interchangeably. Although the origin of the term “antivenom” is obvious, “venin” is French for venom and “antivenin” is traditionally used in certain parts of the world. Wyeth Pharmaceuticals, the maker of Crotaline and Micrurus antivenom, and Merck & Co., Inc., the maker of Latrodectus antivenom, adopted “antivenin” in the brand names for their products. Brand name recognition has largely been responsible for the use of the term “antivenin” in place of “antivenom”. In 1981, the World Health Organization determined the preferred terms for the English language to be “venom” and “antivenom.”

HISTORY

Of the species of spiders of medical importance in the United States, two of the most notable are Latrodectus (*L. mactans*, *L. geometricus*, *L. vaiolus*, *L. hesperus*, and *L. bihopi* are native, while *L. geometricus* was introduced) and Loxosceles. Although commercially available antivenom exists in the United States for treatment of Loxosceles envenomation, antivenom produced for South American Loxosceles spiders demonstrates cross-reactivity with North American species like *L. reclusa*.¹² Currently, one commercially available Latrodectus antivenom exists in the United States. Black widow spider antivenin (Merck & Co., Inc.) (Merck BW-AV) has been available in the United States since its U.S. Food and Drug Administration (FDA) approval in 1936.³ The use of this antivenom in the treatment of Latrodectus envenomations remains controversial, as mortality from these bites is low in the United States,^{7,8,30,32} and complications including death following antivenom administration are rarely reported.^{7,20,31} Most recently, severe production shortages have necessitated emergency release of the product by the manufacturer within 24 hours of notification of a patient with symptoms from a presumed envenomation.¹ Ongoing research and development of an F(ab')₂ antivenom may ameliorate concerns and limitations related to potential adverse events resulting from administration of the Merck antivenom and production shortages limiting availability.¹¹

PHARMACOLOGY

Chemistry, Preparation, and Mechanism of Action

Antivenom for spiders is prepared in a similar manner as other antivenom products by first immunizing animals with non-toxic amounts of venom.^{5,25} Monkeys, horses, goats, sheep, chicken, camels, and rabbits have been used historically to source antivenom.²⁸ The animals are placed on an inoculation schedule to allow gradual production of immunoglobulins, most importantly IgG. Sufficient antibody production usually requires up to 6 weeks. Animal choice for immune serum production is more often dictated by the species availability, financial considerations, and tradition rather than scientific modeling. Horses are used by the majority of antivenom producers, since they are relatively easy to maintain, and large volumes of serum can be obtained at one time without harm. Varying efforts are made during antivenom production to remove animal proteins such as albumin. Antivenoms target, bind, neutralize, and promote elimination or redistribution of toxins from body tissues. To date, no studies have compared immune sera of different animals for human compatibility or tolerance.

The antidotal fraction of an antivenom exists as either whole IgG, Fab, or F(ab')₂. The IgG molecule is composed of two antigen-binding fragments (Fab fragments) that are fused together and attached to the larger complement binding fragment (Fc fragment). It is the larger Fc portion that is generally considered to be the most responsible for immune mediated reactions. Digestion of the disulfide bonds of an IgG molecule with the enzyme pepsin will cleave the Fc fragment, allowing isolation of pure F(ab')₂ fragments (two fused Fab fragments). In contrast, digestion with papain cleaves

the molecule more distally such that a larger Fc portion is removed from two separate Fab fragments. Both Fab and F(ab')₂ molecules can be isolated with affinity chromatography, and the highly antigenic Fc portion discarded. Although Fab and F(ab')₂ are more expensive to produce than their whole immunoglobulin counterparts, they are generally regarded as less allergenic and therefore safer products.

Whole IgG antivenom is the easiest and least expensive to produce. It has a molecular weight of approximately 150 kDa, and is the largest of the three antivenom types. Because of its size, it is the least filterable at the glomerulus and has the smallest volume of distribution. IgG has a longer elimination half-life than either Fab or F(ab')₂.¹⁷

F(ab')₂ has an intermediate size (~100 kDa) and elimination half-life. While lowering the risk of anaphylaxis compared to whole IgG, the F(ab')₂ portion retains much of the allosteric configuration of the original IgG molecule that is lost in when Fab are formed. This configuration theoretically allows for tighter binding to venom. Fab is the smallest (~50 kDa) antivenom molecule in size and is eliminated by the kidneys. It has the largest volume of distribution and a greater ability to reach extravascular compartments. Arachnid venoms that affect the central nervous system have low molecular weights and large volumes of distribution. Fab and F(ab')₂ based antivenoms may therefore be best suited for this function.¹⁷

Immunoglobulin based antivenoms can be given by the intramuscular (IM), intravenous, or subcutaneous route. Intravenous administration achieves rapid peak serum concentrations, and the infusion can be stopped in the event of an allergic reaction.¹⁸ Intramuscular injection has been used when intravenous access is unobtainable.

Pharmacokinetics and Pharmacodynamics

Currently, there is no published pharmacokinetic or pharmacodynamic information available on Merck BW-AV in humans or animals. Graudins and colleagues demonstrated western blot binding of *L. hasselti* (Red Back Spider) Antivenom (RBS-AV) to purified α -latrotoxin and similar protein bands derived from multiple widow spiders (*L. mactans*, *L. hesperus*, *L. lugubris*, *L. tredecimguttatus*, and *L. hasselti*). When co-mixed with the venoms from these species prior to administration, RBS-AV prevented the development of a reproducible and rapid muscle contracture of an in vitro chicken nerve-muscle preparation. A dose-response relationship was observed with varying doses of RBS-AV administration.¹⁶ This confirms a direct in vitro binding effect of RBS-AV against widow spider venoms.

Previous animal studies have demonstrated that intramuscular administration of antivenom demonstrated very low serum venom concentrations.^{35,36} In these rabbit studies of intramuscular administration, F(ab')₂ and IgG had poor bioavailability (36%–42%) and delayed time to peak concentrations of 48 to 96 hours.

Pharmacokinetic and pharmacodynamic characteristics of equine derived antivenoms may differ between species studied. Equine derived antivenom maximum concentrations were greater in cows than in horses, and steady state distribution volumes were higher in cows than in horses in one study. Similar results were observed in rabbit models.³⁷ Pharmacokinetic and pharmacodynamic parameters observed in animal models should therefore be interpreted with caution with regard to behavior of antivenoms in humans.

RBS-AV has been administered intramuscularly to treat human envenomations and clinical effectiveness equivalent to intravenous administration was previously reported.²¹ Subsequent studies, however, demonstrated the absence of RBS-AV in circulating serum up to 5 hours following intramuscular administration. Serum concentrations of RBS-AV were detected within 30 minutes of administration following intravenous administration.²⁴ These results are consistent with animal studies demonstrating little if any effect on circulating venom when antivenoms are given intramuscularly. Additional studies on the pharmacokinetic and pharmacodynamic properties of RBS-AV, Merck Black Widow Antivenom, and F(ab')₂ black widow antivenom (in development) are needed.

ROLE IN LATRODECTUS SPECIES (*L. MACTANS*, *L. HESPERUS*, *L. BISHOPI*, *L. GEOMETRICUS*, *L. VARIOLUS*, *L. INDISTINCTUS*)

Although black widow bites are associated with severe muscle pain, cramping, and autonomic disturbances, mortality remains low.^{7,8,30,33} Symptomatic treatment with muscle relaxants and opioid analgesics is generally effective, although the duration of symptoms following severe envenomation may necessitate hospitalization for 1 to 2 days or more.

The use of Merck Black Widow antivenom may shorten the length of symptoms dramatically, allowing outpatient care in some cases.^{7,30,32,33,39} Studies of reported *Latrodectus* envenomated patients in Australia, however, have demonstrated little clinical difference between *Latrodectus* antivenom and placebo.²¹ In addition, anaphylaxis and other adverse events following the administration of *Latrodectus* antivenom are reported.^{7,20,30,31}

Because of low mortality and potential for adverse events following administration, some authors question the use of black widow antivenom.³⁶ Many toxicologists still believe *Latrodectus* antivenom is safe and effective when used appropriately, and it is generally indicated in cases of severe envenomation where muscle cramping, hypertension,

diaphoresis, nausea, vomiting, and respiratory difficulty are present.⁸

Latrodectus antivenom is also reported to successfully treat priapism complicating severe envenomation.¹⁹ Although the safety of antivenom is not clearly established in the developing fetus, pregnancy is suggested as a consideration for Latrodectus antivenom administration, as the stress of severe pain and muscle cramps may have adverse fetal effects.^{4,38}

Antivenoms for a number of Latrodectus spiders are available worldwide (Table A34–1). A shortage of Merck antivenom prompted the finding that antivenom against *L. hasseltii* (RBS-AV) also neutralizes venom of *L. mactans* in a mouse model.¹⁰ Analatro, a polyvalent F(ab)₂, is an equine-derived antivenom created for *L. mactans* in both Argentina and Mexico that is currently undergoing multi-center clinical trials in Latrodectus envenomated patients in the United States.

TABLE 118–1. Worldwide Availability of Spider Antivenom

Atrax species, Hadronyche species

Latrodectus species

(Black widow spider, Red-backed spider)

Argentina: Anti Latrodectus Antivenom, Instituto Nacional de Produccion de Biologicos, Equine IgG

Australia: Red-backed spider Antivenom, CSL Ltd. Equine F(ab')₂

USA: Antivenin Latrodectus mactans, Merck & Company, Equine IgG

South Africa: SAIMR Spider Antivenom, SAIMR, Equine IgG

Mexico: Aracmyn, Instituto Bioclon, Equine F(ab')₂

Croatia: Antilatrodectus Mactans Tredecimguttatus Serum, Institute of Immunology, Equine IgG

Loxosceles species

(Brown spiders)

Brazil: Antiloxosceles Serum, Centro de Producao e Pesquisas de Immunbiologicos. Equine IgG

Brazil: Soro Antiarachnidico, Instituto Butantan (contains Loxosceles sp, Tityus sp and Phoneutria sp. Antivenom), Equine IgG

Peru: Antiloxosceles Serum, Instituto Nacional de Salud, Centro Nacional de Production de Biologicos, Equine IgG

In a review of 163 cases of presumed *L. hesperus* and *mactans* envenomations, antivenom reduced the mean duration of symptoms from 22 to 9 hours. Symptoms usually subsided within 1 to 3 hours of antivenom administration. The hospital admission rate fell from 52% in those who were managed with opioids and muscle relaxants to 12% in those patients receiving antivenom.⁷ A more recent review demonstrated pain relief in all patients receiving antivenom following symptomatic black widow envenomation.³²

ROLE IN FUNNEL-WEB SPECIES (ATRAX AND HADRONYCHE)

A rabbit IgG based funnel-web spider (*Atrax robustus* and others) antivenom is available in Australia. Since the introduction of the antivenom, no deaths have been reported.²³ Complete response following administration of antivenom was reported in 97% of envenomations in one series.²²

ROLE IN LOXOSCELES SPECIES (L. RECLUSA, L. LAETA, L. RUFESCENS, L. ARIZONICA, L. UNICOLOR)

Envenomation by the brown recluse spider *Loxosceles reclusa* is associated with low, but significant morbidity, particularly in the southeast United States. Anti-*Loxosceles* Fab blocked dermonecrosis in a rabbit model, but only if provided within 24 to 48 hours of envenomation.^{15,34} Although no commercially available antivenom exists in North America for treatment of *Loxosceles* envenomation, antivenom produced against South American *Loxosceles* spiders has cross-reactivity with North American species like *L. reclusa*.¹² The usual late presentation of patients with necrotic lesions from spider bites make antivenom use for *Loxosceles* difficult to study. National laboratories in Brazil and Argentina produce antivenoms for *L. reclusa*, *L. boneti*, and *L. rufescens*.^{5,12}

ADVERSE EFFECTS AND SAFETY ISSUES

Despite the apparent efficacy of antivenom, the decision to give horse serum for a disease with limited mortality should be considered. Death from bronchospasm and anaphylaxis is a rarely reported complication of whole IgG antivenom (Merck) administration,^{7,20,31} as is serum sickness.⁸ Serum sickness is dose-dependent and is less likely when only 1 to 2 vials are typically administered. A detailed review of one case of death following antivenom administration⁷ demonstrates that the antivenom was inappropriately prepared (not diluted) and inappropriately administered (intravenous push rather than slow infusion) to a patient with multiple drug allergies, atopy, and asthma. Resuscitation was further complicated by the development of a pneumothorax. A second death³¹ was reported in a 37 year-old man with history of asthma who received antivenom as an infusion and developed cardiac arrest as a complication of severe anaphylaxis. He died 40 hours after presentation.³¹

In Australia, antivenom to the red-back spider (*L. hasseltii*, CSL Ltd.) is made by immunizing horses for production of F(ab)₂. Horse-derived F(ab')₂ has a lower reported incidence of allergic reactions, with early allergic reactions as low as 0.5% to 0.8%. The incidence of serum sickness is reported at less than 5%.^{40,41} Analatro (under evaluation) is a similar F(ab')₂ product which would be anticipated to be a safer antivenom than the currently available Merck whole IgG product.

A review of the US National Poison Data System (NPDS) demonstrated a 3.4% rate of adverse drug reactions (ADRs) following administration of the Merck *Latrodectus* antivenom.³⁰ This is consistent with previously reported rates of ADRs following black widow antivenom administration.⁸ Directly attributing these complications to administration of antivenom is difficult as these patients received multiple therapies including opioids, benzodiazepines, and calcium salts preceding antivenom administration, and NPDS does not attribute an ADR to a specific therapy. Similarly, the nature of these ADRs is not described in NPDS. However, it is noteworthy that no deaths occurred in 374 instances of use and only five patients received antihistamines, suggesting acute hypersensitivity reactions to the Merck black widow antivenom to be uncommon and that this antivenom is generally safe. Similarly, a review of 96 assessable instances of black widow antivenom administration over a 10 year period in a single state similarly demonstrated a low rate of adverse reactions. Four (4%) patients in the series had adverse effects ascribed to antivenom administration. These reactions were generally mild and included myalgias, fatigue, generalized paresthesias, flushing, and urticarial rash. There were no cases of dyspnea, angioedema, bronchospasm, hypotension, or death.³² This low rate of severe adverse reactions and lack of death suggests that Merck black widow antivenom is a safe product when prepared and administered correctly to patients without underlying atopy, asthma, or drug allergies.

PREGNANCY AND LACTATION

Black widow envenomations during pregnancy are relatively rare. Of 12,640 patients envenomated by a blackwidow spider, 97 (3%) were pregnant. When compared with nonpregnant women, no significant differences were observed in recommended or administered treatments including the use of antivenom.⁶ There are six reported cases of *Loxosceles* envenomations in pregnant women. They were all managed with supportive therapy including analgesics, antihistamines, and short course low dose steroids. Pregnancy outcomes were favorable in all reported cases.^{2,14} Merck black widow antivenom is Pregnancy Category C. It is not known whether antivenom is excreted in human milk.

DOSING AND ADMINISTRATION

The starting dose of the Merck antivenom is one vial (2.5 mL) diluted in 50 mL of saline for intravenous administration. Although black widow spider antivenom can also be given IM, this route carries the disadvantage of slower, more erratic absorption, less control over the rate of administration, and the inability to stop the administration should an allergic reaction occur. In addition, recent studies suggest IM injection of antivenom may not yield significant serum concentrations.²⁴ For these reasons, the intramuscular route is not routinely recommended.

The initial dose of antivenom in funnel-web spider envenomation is two vials in patients with any signs or symptoms of envenomation. Patients with acute respiratory distress syndrome or decreased consciousness should receive four vials.²⁹

For severe cases, the following protocol has been suggested.²⁹ Two vials (each containing 100 mg of rabbit IgG) of antivenom are administered very slowly intravenously. The dose can be repeated in 15 minutes if no improvement occurs. The dose should be doubled for severe cases. A rapid response should occur. Administration of antivenom should be repeated until symptoms are completely reversed.¹³ *Atrax robustus* envenomations may require multiple infusions of antivenom. The recommended dosage for children is the same as for adults.

FORMULATION AND ACQUISITION

Each vial of the Merck product contains 6000 antivenom units standardized by biologic mouse assay. Because *Latrodectus* venoms are virtually identical by immunologic and electrophoretic mechanisms, antivenom created for *L. mactans* is presumed to be effective in other species of *Latrodectus* as well.²⁷

Latrodectus antivenin is supplied as a white to gray crystalline powder in vials containing not less than 6000 antivenin units with thimerosal 1:10,000 added as a preservative, along with a 2.5 vial of sterile diluent for reconstitution. The antivenin must be stored and shipped at 2 to 8°C (36–46°F), but never frozen. The reconstituted antivenin color ranges from light straw to very dark iced tea, although color has no effect on potency.^{2a}

Emergency supplies of *Latrodectus* antivenin are available for patients with symptoms due to a bite by the black widow spider within 24 hours of contacting Merck. The Antivenom Index, maintained by the Association of Zoos and Aquariums (<https://www.aza.org/antivenom-index/>) and accessible by the nation's Poison Control Centers, might also serve as a resource.

SUMMARY

- The decision to use spider antivenom must be individualized to the patient and clinical manifestations.
- Because mortality following black widow envenomation is low, antivenom is reserved for cases where symptoms are severe or do not respond to other therapies, and after a frank discussion with the patient of possible adverse effects.
- Although a large body of literature suggests that Merck black widow antivenom is safe when properly prepared and administered to patients without asthma. Adverse effects including severe anaphylaxis and death are reported.
- A new, purified F(ab)₂ black widow spider antivenom is in clinical development, but is currently unavailable.

A35 ANTIDOTES IN DEPTH

Antivenom: Scorpion

Michael A. Darracq and Richard F. Clark

INTRODUCTION

Centruroides exilicauda (formerly known as *Centruroides sculpturatus*) is the only scorpion of medical importance in the United States. It is indigenous to the deserts of Arizona but also can be found in Texas, New Mexico, California, and Nevada.¹¹ Occasionally, envenomations occur in nonindigenous areas of the country from “stowaway” scorpions in travelers’ luggage.³²

HISTORY

Arizona poison centers receive several thousand calls annually for scorpion stings. Although the incidence of morbidity with these envenomations is significant, no deaths associated with the toxic effects of scorpion venom have been reported in the United States for almost 50 years. However, deaths are associated with anaphylactic reactions to scorpion venom.⁷ Antivenom for the *Centruroides* spp. was produced in horses in Mexico as early as the 1930s.¹¹ In 1947, antivenom was produced from rabbits and cats immunized with *C. sculpturatus* and *Centruroides gertschi*.²⁹ The Antivenom Production Laboratory at Arizona State University (APL-ASU) began producing antivenom to *C. sculpturatus* in goats in 1965. This antivenom was used for treatment of scorpion stings in Arizona until 2004, when production ceased and stockpiles expired. In June 2000, Silanes Laboratory received orphan drug status for a *Centruroides* scorpion antivenom, an equine-derived F(ab')₂ from *Centruroides limpidus*, *Centruroides noxius*, *Centruroides suffusus suffusus*, and *Centruroides meisei* (formerly known as *Centruroides elegans*) manufactured by Instituto Bioclon of Mexico, and referred to as Anascorp. In August 2011, Anascorp was approved by the US Food and Drug Administration (FDA) for the treatment of *Centruroides exilicauda* envenomations.¹⁵

PHARMACOLOGY

Antivenom for scorpions is prepared in the same manner as other antivenom products (Antidotes in Depth: A34 and A37).

Pharmacokinetics and Pharmacodynamics

In a study of 8 healthy patients (6 males and 2 females, age 17–26 years) without prior scorpion envenomation, a bolus intravenous dose of 47.5 mg of Anascorp was administered. Serial blood samples were collected over 21 days. Measured pharmacokinetic parameters (mean ± standard deviation) included: area under the curve (AUC), 706 ± 352 µh/mL; clearance, 83.5 ± 38.4 mL/h; half-life, 159 ± 57 hours; and steady state volume of distribution (Vd_{ss}), 13.6 ± 5.4 L.³³

ROLE IN CENTRUROIDES SPECIES

One vial of Anascorp antivenom contains sufficient F(ab')₂ to neutralize 150 mouse LD₅₀ of *Centruroides* venom.²⁵ Safety and efficacy are documented in both animals and humans.^{1,8,9,10} In the FDA review and subsequent approval of Anascorp, six trials were submitted for consideration. Only one study was prospective, randomized, double-blinded, and controlled and demonstrated a clear benefit in reduction of signs and symptoms of scorpion envenomation by 4 hours postadministration (8/8 vs. 1/7), reduction in quantity of sedative administered (mean midazolam dose of 0.1 mg/kg (0.0–0.2 mg/kg) versus 4.6 mg/kg (0.1–16.7 mg/kg), and absence of free serum venom concentrations at one hour after administration (mean 0.0 vs. 2.65 ng/mL).⁸

One retrospective trial using historical controls was included as representative of clinical outcomes in the absence of

antivenom administration. This trial demonstrated the need for exceedingly large dose of sedatives to treat the inability to walk and respiratory distress due to envenomation with a mean time to discharge of 12.6 hours without administration of scorpion antivenom.¹¹

One large (n = 1534), unpublished and open label study was also included for review. The majority (1204/1534) of patients were children (0.7 months–18 years) and male (52.3%). In 1396/1425 patients, the mean time to resolution of clinically important signs of envenomation following Anascorp administration was 1.42 hours (0.2–20.5 hours). Children reportedly improved slightly faster than adults (1.28 ± 0.8 hours vs. 1.91 ± 1.4 hours). Of the 1534 patients included in the study, 95% had relief of systemic signs associated with Centruroides envenomation within 4 hours of Anascorp administration.^{9,14}

Three additional open label trials (AL-02/04-adult patients, AL-02/05-pediatric patients, and AL-02/06-pediatric patients) with the use of the Instituto Bioclon of Mexico product Alacramyn (Alacramyn is the Mexican equivalent of Anascorp) were reported by the study sponsors to demonstrate 100% resolution of symptoms by 4 hours following administration of antivenom.¹⁴

ROLE IN LEIURUS SPECIES

The Leiurus quinquestriatus scorpion is indigenous to Africa, Asia, and the Middle East, including Egypt, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, and Turkey. Antivenom to L. quinquestriatus is currently made in France, Germany, Israel, Saudi Arabia, Egypt, Tunisia, and Turkey (Table A35–1).

<p>Eusecorpius carthothleus, Italian</p> <p>Turkey: Scorpion Antivenom, Refik Saydam Hygiene Center (RSHC), Equine F(ab)₂,</p>	<p>Palaemonius species</p> <p>India: Monovalent Red Scorpion Antivenom, Central Research Institute, Equine F(ab)₂,</p> <p>Parabuthus species</p> <p>South Africa: SAIMR Scorpion Antivenom, South African Vaccine Producers (Pty) Ltd. (SAMP) Equine F(ab)₂,</p>	<p>Centruroides species (<i>elegans</i>, <i>gertschi</i>, <i>limpulus</i>, <i>suffusus</i>, <i>naxosus</i>, <i>virilicauda</i>)</p> <p>Mexico: Soro Antialacran Alacramyn, Instituto Bioclon, Equine F(ab)₂,</p> <p>United States: Anascorp, Centruroides (Scorpion) Immune F(ab)₂, (Equine) Injection, Instituto Bioclon, Equine F(ab)₂,</p>

In observational studies, an intravenous infusion of 5 to 20 mL of Leiurus antivenom was needed to control venom effects, and only patients given antivenom within the first several hours demonstrated significant benefit.^{2,20} The rate of allergic reactions for the Turkish antiscorpion antivenom is reported to be 1.6% to 6.6%.²⁰ The recommended dose of the Israeli L. quinquestriatus antivenom is 5 to 15 mL for intravenous use, although several authors report lack of clinical efficacy of this particular antivenom.^{5,16,30}

L. quinquestriatus antivenom was successfully used to treat a 2 year-old boy with envenomation by Androctonus crassicauda. Symptoms resolved 2 hours after antivenom administration.²⁸

ROLE IN TITYUS SPECIES

Tityus species of scorpions are endemic to South America, particularly Brazil. An F(ab)₂ antivenom for Tityus serrulatus is available from Fundação Ezequiel Dias (FUNED), in Belo Horizonte, Brazil. The usual dose of the antivenom is 20 mL as an intravenous infusion.¹³

In a series of 18 patients with T. serrulatus envenomation treated with antivenom, vomiting and local pain decreased within 1 hour, and cardiorespiratory manifestations disappeared within 6 to 24 hours in all patients except the two presenting with acute respiratory distress syndrome.¹³ Sixteen patients recovered completely by 24 hours. The Instituto Buntantan in Brazil also produces Soro antiarachnidico and Soro antiscorpionico for treatment of Tityus spp.

Role in Androctonus Species

Scorpion antivenom in South Africa is an equine-derived antivenom available from the South African Vaccine Producers, formerly South African Institute for Medical Research (SAIMR), Johannesburg, South Africa. ScorpiFAV, produced by Aventis Pasteur, is produced for treatment of *Androctonus* spp, *B. occitanus*, and *L. quinquestriatus*.

Buthus tamulus monovalent red scorpion antivenom serum produced by Central Research Institute of India is an equine-derived lyophilized antivenom for the venom of *Mesobuthus tamulus*. The manufacturer recommends a dosage of one vial, although a dose of five vials decreased mortality significantly in one study.^{22,31}

In Pakistan, the treatment of scorpion stings was modified in 1991 to include the administration of five vials of antivenom. A retrospective case series of 950 patients treated with and without antivenom was compared to 968 cases treated after the five vial protocol was initiated. A statistically significant decrease in mortality was demonstrated. The last recorded death in Pakistan resulting from a scorpion sting occurred in 1991 in a patient who did not receive antivenom.³¹

Parabuthus spp antivenom from South African Vaccine Producers is an equine-derived antivenom to *Parabuthus* spp. In one study, antivenom was unavailable for a period of time allowing for a unique design of matched pair of patients. Patients who received antivenom had a significant decrease in hospital stay after receiving one (5 mL) vial. Pain, hypersalivation, fasciculations, tremor, and bladder distension responded best to antivenom, whereas dysphagia, ptosis, and local swelling were more resistant.⁶ More recent studies from India show equivocal results for scorpion envenomation treated with antivenom when compared to treatment with prazocin.^{4,26}

The unavailability of specific antivenoms often necessitates symptomatic treatment or use of a comparable foreign antivenom. In a study of 72 moderate scorpion stings in Para, Brazil, 33% who met criteria for antivenom administration did not receive treatment because of unavailability of the antivenom.²⁷

ADVERSE EFFECTS AND SAFETY ISSUES

Hypersensitivity reactions to Anascorp and other equine derived antivenoms may occur following administration. Patients with known equine protein allergies or previous exposure to Anascorp or other equine derived antivenoms or antitoxins may be at increased risk due to previous sensitization. No deaths were reported in clinical trials of Anascorp. Adverse effects reported from cumulative clinical trial data revealed that 2.2% of patients experienced severe adverse reactions (respiratory distress, aspiration, hypoxia, ataxia, pneumonia, and eye swelling) following Anascorp administration. However, these symptoms occurred in the setting of acute *Centruroides* envenomation, limiting the direct attribution of symptoms to antivenom administration alone. The most common adverse effects reported included vomiting (4.7%), pyrexia (4.1%), rash (2.7%), nausea (2.1%), and pruritus (2%).¹⁴ The presence of cresol as an injectable excipient may increase localized reactions and generalized myalgias following administration. No drug interaction studies have been conducted with Anascorp.

PREGNANCY AND LACTATION

Anascorp is Pregnancy Category C. Animal reproduction studies have not been conducted, and it is unknown whether Anascorp may cause fetal harm when administered to pregnant women. Reproductive capability postadministration similarly has not been assessed. Anascorp should only be administered in pregnant women if clearly needed for alleviation of symptoms and after other therapies have been utilized. It is unknown whether Anascorp is excreted in human breast milk.¹⁴

DOSING AND ADMINISTRATION

Anascorp is the only US FDA approved treatment for the clinical signs and symptoms of *Centruroides* scorpion envenomation. These include, but are not limited to, loss of motor control, roving or abnormal eye movements, slurred speech, respiratory depression, and excessive oral secretions. Package insert dosing recommendations (FDA) are three vials administered intravenously over 10 minutes after reconstitution (5 mL sterile 0.9% sodium chloride solution/vial) and dilution to a total volume of 50 mL. Additional vials may be administered every 30 to 60 minutes as needed for symptom control. The price of Anascorp may vary from hospital to hospital. In one survey of Phoenix, Arizona hospitals, the charge per vial was between \$7900 and \$15,120.³

FORMULATION AND ACQUISITION

Anascorp is supplied as a sterile lyophilized preparation in a single-use vial. When reconstituted, each vial contains not more than 24 milligrams per milliliter of protein, and not less than 150 mouse LD50 neutralizing units. Anascorp should not

be frozen, but stored at room temperature up to 25°C (77°F).¹⁴

The Antivenom Index, maintained by the Association of Zoos and Aquariums (<https://www.aza.org/antivenom-index/>) and accessible by the nation's Poison Control Centers, may serve as a resource in the event of difficulty obtaining antivenom. The World Health Organization's World Directory of Poison Centres (http://www.who.int/gho/phe/chemical_safety/poisons_centres/en/) might assist those outside of the U.S. to source more exotic antivenoms.

SUMMARY

- The indications for antivenom administration following scorpion stings remain controversial.
- The decision to use antivenom should be individualized to the patient, weighing the risk of giving an immune serum, the level of available supportive care, the risks and costs of supportive care alone, and the cost of obtaining or importing antivenom.
- Scorpion antivenom administration for some species may not improve outcome.
- The preferred route of administration of these products is intravenous. One to two vials is the recommended dose for most scorpion antivenoms; higher doses may be needed to alleviate symptoms in some cases.

119 MARINE ENVENOMATIONS

D. Eric Brush

Human contact with venomous marine creatures is common and may result in serious harm from biological toxins or mechanical injury inflicted by the stinging apparatus. Significant morbidity results from envenomation by spiny fish, cone snails, octopi, sea snakes, and several species of jellyfish. Despite advances in basic science research regarding the biochemical nature of marine toxins and their mechanisms of action, our knowledge of the pathophysiology related to clinical syndromes in humans and the optimal therapies for human envenomation remain limited. Evidence for effective treatment is primarily derived from in vitro and in vivo animal research without the benefit of controlled human trials. However, current research in toxinology coupled with clinical observations allows the development of cogent treatment guidelines for victims of marine envenomation.

INVERTEBRATES

Cnidaria

The phylum Cnidaria (formerly Coelenterata) includes more than 9000 species, of which approximately 100 are known to injure humans. They are commonly referred to as jellyfish; however, their phylogenetic designations separate “true jellyfish” and other organisms into distinct classes (Table 119–1; Fig 119–1A). All species possess microscopic cnidae (the Greek knide means nettle), which are highly specialized organelles consisting of an encapsulated hollow barbed thread bathed in venom. Thousands of these stinging organelles, called nematocysts (or cnidoblasts), are distributed along tentacles. A trigger mechanism called a cnidocil regulates nematocyst discharge. Pressure from contact with a victim’s skin, or chemical triggers such as osmotic change, stimulates discharge of the thread and toxin from its casing. Penetration of flesh leads to intradermal venom delivery. Nematocysts of most Cnidaria are incapable of penetrating human skin, rendering them harmless. Cnidaria causing human envenomation, such as the box jellyfish, discharge threads capable of penetrating into the papillary dermis.¹³⁶

TABLE 119–1. Characteristics of Common Cnidaria

<i>Latin Name</i>	<i>Common Name</i>	<i>Habitat*</i>
Cubozoa class		
<i>Chironex fleckeri</i> [§]	Box jellyfish	Tropical Pacific Ocean, Indian Ocean, Gulf of Oman
<i>Carukia barnesi</i> [§]	Inukandji jellyfish	North Australian coast
<i>Chiropsalmus spp</i> [§]	Sea wasp or fire medusa	North Australian coast, Philippines, Japan, Indian Ocean, Gulf of Mexico, Caribbean
<i>C. quadrigatus</i>		
<i>C. quadrumanus</i>		
<i>Carybdea alata</i>	Hawaiian box jelly fish	Hawaii
<i>Carybdea rastoni</i>	Jimble	Australia
Hydrozoa class		
<i>Physalia physalis</i> [§]	Portuguese man-of-war	Eastern US Coast from Florida to North Carolina, Gulf of Mexico, Australian coastal waters (rare reports)
<i>Physalia utriculus</i>	Bluebottle	Tropical Pacific Ocean, particularly Australia
<i>Millepora albicornis</i>	Fire coral	Widespread in tropical waters, including Caribbean
Scyphozoa class		
<i>Chrysaora quinquecirrha</i>	Sea nettle	Chesapeake Bay, widely distributed in temperate and tropical waters
<i>Stomolophus meleagris</i>	Cabbage head or cannonball jelly fish	Gulf of Mexico, Caribbean
<i>Stomolophus nomurai</i> [§]		Yellow Sea between China and South Korea
<i>Cyanea capillata</i>	Lion's mane or hair jelly fish	Northwest US coast up to Arctic Sea, Norwegian and British coastlines, as well as Australia
<i>Pelagia noctiluca</i>	Mauve stinger or purple-striped jelly fish	Wide distribution in tropical zones
<i>Liruche unguiculata</i>	Thimble jelly fish	Florida, Mexico, and Caribbean
Anthozoa[§] class		
<i>Anemonia sulcata</i>	European stinging anemone	Eastern Atlantic, Mediterranean, Adriatic Sea
<i>Actinodendron plamosum</i>	Hell's fire anemone	South Pacific
<i>Actinia equina</i>	Beadlet anemone	Great Britain, Ireland

[§]Represents most common areas where stings are reported. [§]Well-documented human fatalities.

FIGURE 119-1 (A) North Atlantic Portuguese man-of-war *Physalia physalis* with multiple tentacles dangling in the water. The tentacles filled with venomous nematocysts extend several meters in length. (Used with permission of Adam Lavery. Reproduced with permission from Knoop et al., *The Atlas of Emergency Medicine*, 3e (c) 2010, McGraw-Hill Inc., New York, New York.) (B) Linear eruption from contact with an unidentified jellyfish in the South Atlantic Ocean.

Cubozoa. Members of the class Cubozoa are not true jellyfish. Animals in the Cubomedusae order have a cube-shaped bell with four corners, each supporting between 1 and 15 tentacles. Species from this order produce the greatest morbidity and mortality of all Cnidaria. The order has two main families of toxicologic importance: Chirodropidae and Carybdeidae.

The Chirodropidae family is well known for the box jellyfish *Chironex fleckeri* (Greek cheiro means hand, Latin nex means murderer; therefore, “assassin’s hand”). When full grown, its bell measures 25 to 30 cm in diameter and 15 tentacles are attached at each “corner” of the bell. These tentacles may extend up to 3 m in length. Another member of this family is *Chiropsalmus quadrigatus*, the sea wasp. Its pale blue color makes detection in water nearly impossible.

The Carybdeidae family is most notable for *Carukia barnesi*, the Irukandji jellyfish.⁶¹ Its small size, with a bell diameter of only 2.5 cm, limits detection in open waters.

Hydrozoa. Members of the Hydrozoa class are also not true jellyfish. The order Siphonophora (Physaliidae family) includes two unusual creatures of toxicologic concern: *Physalia physalis*, the Portuguese man-of-war, and its smaller counterpart, *Physalia utriculus*, the bluebottle. They are pelagic (floating) colonial Hydrozoa, meaning they exist as a colony of multiple hydroids in a formed mass. The easily recognizable blue sail that floats above the surface of the water is filled with nitrogen and carbon monoxide. Tentacles of *P. physalis* may reach lengths exceeding 30 m and contain more than 750,000 nematocysts in each of its numerous tentacles (up to 40). *P. utriculus* has only one tentacle that measures up to 15 m.

The Milleporina order includes the sessile *Millepora alcicornis* (fire coral) that exists as a fixed colony of hydroids. It appears much like true coral and has a white to yellow-green lime carbonate exoskeleton. Small tentacles protrude through minute surface gastropores. The overall structure ranges from 10 cm to 2 m.

Scyphozoa. True jellyfish belong to the class Scyphozoa and are extremely diverse in size, shape, and color. Common varieties known to envenomate humans are *Cyanea capillata* (lion’s mane or hair jelly), *Chrysaora quinquecirrha* (sea nettle), and *Pelagia noctiluca* (mauve stinger). The mauve stinger is easily recognized; it appears pink in daylight and phosphorescent at night. Larvae of *Linuche unguiculata* cause sea bather’s eruption (SBE). The larvae are pinhead sized and are seen only when they are grouped in large numbers near the surface of the water.

Anthozoa. The Anthozoa class has a diverse membership, including true corals, soft corals, and anemones. Only the anemones are of toxicologic importance. They are common inhabitants of reefs and tide pools and attach themselves to rock or coral. Armed with modified nematocysts known as sporocysts located on their tentacles, they produce stings similar to those of organisms from other Cnidaria classes.

History and Epidemiology. Stings from Cnidaria represent the overwhelming majority of marine envenomations. In Australia, approximately 10,000 stings per year are recorded from *Physalia* spp alone.⁵⁶ Most Cnidaria stings occur during the warmer months of the year. Stings occur with greatest frequency on hotter-than-average days with low winds, particularly during times of low precipitation. “Stinger nets” are used in high-risk areas of the Australian coastline; however, one study reported that 63% of stings requiring medical attention occurred within netted waters.⁸⁸ Each stinger season, the Royal Darwin Hospital in Australia treats approximately 40 patients with stings.⁴² A prospective evaluation of stings presenting to that hospital during a 12-month period from 1999 to 2000 revealed that 70% resulted from the box jellyfish. The remaining 30% involved other Cubozoa such as *C. barnesi*.¹⁰⁹ Although this finding may indicate a predominance of box jellyfish as the cause of stings, it also suggests that stings from box jellyfish are more severe and require medical attention with greater frequency than stings from other species of Cnidaria.

Stings from *C. barnesi*, the organism originally identified as the cause of Irukandji syndrome, were initially considered unique to Australia. However, an unidentified species produced three cases of an Irukandjilike syndrome in the Florida Keys.⁶⁹ More recent reports identify an Irukandjilike syndrome north of Australian waters in the Torres Strait,¹⁰⁰ suggesting a more diverse geographical distribution and possibly more than one responsible organism.

Cases of SBE, a stinging rash evoked by contact with Cnidaria larvae, occur in clusters. Variation in intensity and frequency occurs from year to year as exemplified by a 25-year hiatus during which no cases were reported in Florida.¹⁴⁴ In 1992, more than 10,000 cases of SBE occurred in south Florida, with similar peaks in the 1940s and 1960s. Cases of SBE also are reported in Cuba, Mexico, the Caribbean, and occasionally as far north as New York.

Cnidaria common to the United States include the Portuguese man-of-war and sea nettle. Other species are widely distributed throughout the tropical and temperate waters of the globe (Table 119–1). Locations with documented Cnidaria-related deaths include the United States (Florida, North Carolina, Texas), Australia, the Indo-Pacific region (Malaysia, Langkawi Islands, Philippines, Solomon Islands, Papua New Guinea), and the coast of China.^{12,23,56,87,135} Since 1884, approximately 70 deaths in Australia are attributed to *C. fleckeri*. An estimated two to three deaths per year occur in Malaysia from an unknown species. Approximately 20 to 40 deaths are reported yearly in the Philippines from an unidentified species of the Chirodropidae family. Three deaths are well documented from *P. physalis* in the United States (Florida, North Carolina). One death from *Chiropsalmus quadrumanus* occurred along the coast of Texas. Eight fatalities in the Bohai waters of China (Yellow Sea) are reported from *Stomolophus nomurai*. Although Chirodropidae are found off the

western coast of Africa, no fatalities in that region are documented in the medical literature.

Pathophysiology. Cnidaria venoms contain a variety of components that may induce dermatonecrosis, myonecrosis, hemolysis, or cardiotoxicity, depending on the particular species. In rats, *C. fleckeri* venom evokes transient hypertension, followed by hypotension and cardiovascular collapse within minutes.¹¹⁶ Cardiac effects in animals include negative inotropy, conduction delay, ventricular tachycardia, and decreased coronary artery blood flow.⁴² However, experiments using the purest venom extracts without contamination from tentacle material demonstrate cardiovascular collapse without electrocardiographic changes.¹¹⁶ *C. fleckeri* venom also possesses dermatonecrotic and hemolytic fractions, although hemolysis is not documented in humans.⁹ Two myotoxins from *C. fleckeri* cause powerful sustained muscle contractions in isolated muscle fibers.⁴⁶ Isolated heart models using *C. fleckeri* venom suggest its mechanism of action is nonspecific enhancement of cation conductance leading to increased Na⁺ and Ca²⁺ entry into cells.¹⁰⁵ Other in vitro work confirms increased Na⁺ permeability in cardiac tissue.⁶³

C. barnesi, the Irukandji jelly, likely induces its dramatic vasopressor effects via catecholamine release. In rats, the venom produces a pressor response that is blocked by α_1 -adrenergic antagonism.¹¹⁵ The pressor response is not dose dependent; therefore, catecholamines in the venom are an unlikely cause. In vitro experiments suggest a Na⁺ channel modulator effect leading to massive catecholamine release.¹⁵⁷ No electrocardiographic abnormalities occurred in envenomated rats.

Venom from *Physalia* spp blocks neural impulses in isolated frog sciatic nerve⁸² and produces ventricular ectopy, cardiovascular collapse, hyperkalemia, and hemolysis in dogs.⁷² *Physalia* spp venom inhibits Ca²⁺ entry into the sarcoplasmic reticulum.⁸² Similar mechanisms are proposed for *Chrysaora*, *Chiropsalmus*, and *Stomolophus*. *C. quinquecirrha* venom, which contains a 150-kDa polypeptide that induces atrioventricular block¹⁹ and produces myocardial ischemia, hypertension, dysrhythmias, and nerve conduction block,^{24,25} as well as hepatic and renal necrosis.¹⁰⁴ *C. quinquecirrha*-induced hepatotoxicity is believed to be a direct toxin effect not mediated by pore formation or Ca²⁺ channel effects.⁷⁴ Equinatoxin II (EqII), found in the venom of the anemone *Actinia equina*, creates pores in cell membranes leading to hemolysis.¹ This protein belongs to a group of anemone lysins known as actinoporins that bind to cell membranes and form pores via oligimerization.⁹³

An immune-mediated response to venom may explain some sting-related symptoms. Elevated serum anti-sea nettle immunoglobulin IgM, IgG, and IgE may persist for years in patients with exaggerated reactions to stings compared with controls.²⁰ A direct correlation between titers against *Chrysaora* and *Physalia* and severity of a visible skin reaction to envenomation strongly suggests an allergic component.¹²⁶ Elevated IgG titers were demonstrated in one death from *P. physalis*.¹³⁵ Dermatonecrosis from *C. fleckeri* may involve the release of leukotrienes and other arachidonic acid derivatives as well as direct toxin-mediated cell damage.⁴³ Postenvenomation syndromes may result from an exaggerated, prolonged, aberrant T-cell response.^{26,27} Erythema nodosum following a sting from *P. physalis* lends further support to an immunologic component.⁵ SBE displays a characteristic delay in onset of symptoms and can be effectively treated with steroids, suggesting a primary immune-mediated process. This is further supported by histopathology revealing the presence of perivascular and interstitial infiltrates with lymphocytes, neutrophils, and eosinophils.¹⁵⁸

Clinical Manifestations. Most patients with stings are treated beachside and never require hospitalization. The vast majority of patients with stings who seek medical care do so because of severe pain without evidence of systemic poisoning.⁴² However, severe systemic manifestations may develop following stings from *C. fleckeri*, *C. barnesi*, *P. physalis*, and a few other Cnidaria.

Envenomation by *C. fleckeri* inflicts the most severe pain and is frequently associated with systemic toxicity. Common symptoms include immediate severe pain, followed by an erythematous whiplike linear rash with a “frosted ladder” appearance. The pain often is excruciating and may require parenteral analgesia. Systemic symptoms include nausea, vomiting, muscle spasms, headache, malaise, fever, and chills. Pain generally abates over several hours, although the rash may persist for days. In a prospective series of *C. fleckeri* stings, 58% manifested delayed hypersensitivity reactions in the form of an itchy maculopapular rash at 7 to 14 days.¹⁰⁹ Most resolved spontaneously; some were treated with antihistamines and topical corticosteroids.

Fatality is documented to occur with only 4 m of tentacle markings.¹³⁶ Death is rapid, preventing many victims from reaching medical care, or even the shore.⁸⁶ Cardiac arrest and pulmonary edema may develop in young, healthy patients without prior cardiopulmonary disease.^{78,92,156} Survival is possible with immediate cardiopulmonary resuscitation (CPR).¹⁵⁵ *C. quadumanus*, a close relative of the box jellyfish, induces symptoms that are similar to *C. fleckeri* stings, including pulmonary edema and death.¹²

Previous reports suggesting a 15% to 20% fatality rate¹²² following *C. fleckeri* envenomation likely represent a gross overestimation given the low number of documented fatalities in the context of the extraordinary number of yearly stings. A prospective study of stings from Cubozoa over one year in Australia revealed no dysrhythmias, pulmonary edema, or

death.¹⁰⁹ No patient received antivenom, and analgesia was the only pharmacotherapy implemented. Hospital admission was not required for any victim. Although most victims suffer only local severe pain, serious systemic toxicity occurs occasionally, and may include vertigo, ataxia, paralysis, delirium, syncope, respiratory distress, pulmonary edema, hypotension, and dysrhythmias. In a series of 10 reported deaths from *C. fleckeri*, all occurred in children, suggesting vulnerability due to lower body mass and thinner dermis.⁴²

Irukandji syndrome is a severe form of envenomation following Cubozoa stings from *C. barnesi*.⁷⁵ Individuals afflicted often notice a mild sting while they are in the water; however, skin findings typically are absent. Severe systemic symptoms develop within 30 minutes and mimic a catecholamine surge including tachycardia, palpitations, hyperpnea, headache, pallor, restlessness, apprehension, sweating, and a sense of impending doom. A prominent feature is severe whole-body muscle spasms that come in waves and preferentially affect the back. Spasms are described as unbearable and frequently require parenteral analgesia. Symptoms generally abate over several hours. Admission rates in patients presenting to medical care can exceed 50%.⁸⁸ Hypertension is universal and may be severe, with systolic blood pressures well over 200 mm Hg. Two fatalities are described involving severe hypertension (systolic 280/150 mm Hg and 230/90 mm Hg) resulting in intracranial hemorrhage.^{52,75} Hypotension frequently follows, requiring vasopressor support. Pulmonary edema can develop within hours. Echocardiograms consistently reveal global ventricular dysfunction.^{90,95} Restored cardiac function typically returns after several days.⁸⁹ A retrospective review of 116 cases of Irukandji presenting to Cairns Base Hospital identified elevated troponin I measurements in 22% of patients.⁷⁵ Electrocardiographic changes are described as nonspecific.

P. physalis envenomation typically induces severe pain, bullae, and skin necrosis (Fig. 119–1B). Systemic symptoms include weakness, numbness, anxiety, headache, abdominal and back spasms, lacrimation, nasal discharge, diaphoresis, vertigo, hemolysis, cyanosis, acute kidney injury, shock, and, rarely, death. Some patients experience local numbness and paralysis of the affected extremity that resolves spontaneously.⁷⁶ As with serious *C. fleckeri* stings, cardiovascular collapse and death can occur within minutes of envenomation.²³ However, fatalities can be delayed several days following envenomation and relate to complications such as myocardial infarction and aspiration pneumonitis.¹³⁵ An unusual presentation is reported of a 4 year-old child who was stung along the North Carolina coast and developed massive hemolysis requiring transfusions, followed by acute kidney failure necessitating temporary hemodialysis.⁷⁰ In contrast to *P. physalis*, *P. utriculus* stings typically are mild, although systemic toxicity occasionally develops.⁵⁸

M. alcicornis (fire coral) is a common cause of stings in southern United States and Caribbean waters. While a member of the same phylogenetic class as *P. physalis*, it produces far less significant injuries. It is a nuisance to divers who touch the coral and suffer moderate burning pain for hours. Untreated pain generally lessens within 90 minutes, with skin wheals flattening at 24 hours and resolving within one week. Hyperpigmentation may persist for up to 8 weeks.¹⁶ The feather hydroid is the most numerous of the Hydrozoa and produces only mild stings.⁹⁷

True jellyfish typically are less harmful to humans than Cubozoa or Hydrozoa. However, systemic toxicity and occasional deaths are reported from certain species such as *S. nomurai*, *C. capillata*, *C. quinquecirrha*, and *P. noctiluca*. *Stomolophus meleagris* is a common cause of stings; however, its weak venom produces only minor injury.⁴

Larvae of *Linuche unguiculata* are the primary cause of a pruritic papular eruption on the skin of sea bathers in Florida, occurring mostly in areas covered by a bathing suit as a result of larvae trapped under the garments. Cases were first noted in 1949 and dubbed SBE.¹²⁷ The larvae appear as pin-sized brown to green-brown spheres in the upper 2 inches of the water and are typically unnoticed. In a retrospective review, 50% of people reported a stinging sensation while they were in the water, and 25% reported itching upon exiting the water.¹⁵⁸ The remainder of patients developed symptoms within 11 hours. Skin lesions develop within hours of itching and appear as discrete, closely spaced papules, with pustules, vesicles, and urticaria. Most lesions occur in areas covered by the bathing suit where the larvae accumulate; however, folds of skin such as the axilla, breasts, and neck may be affected. Itching often is severe and prevents sleep. New lesions may continue to develop over 72 hours. The average duration of symptoms is just under 2 weeks, and a small percentage of patients experience a recurrence of lesions several days later. Systemic symptoms such as chills, headache, nausea, vomiting, and malaise may occur.

Following stings from sea anemones, victims may develop either immediate or delayed pain. Skin findings range from mild erythema and itching to ulceration. A review of 55 stings from *Anemonia sulcata* presenting to a hospital in Yugoslavia (Adriatic Sea) revealed that, in addition to the local skin findings, many patients suffered nausea, vomiting, muscle aches, and dizziness.⁹⁴ Larvae of the anemone *Edwardsiella lineata* also cause SBE among ocean swimmers in Long Island, New York. The hell's fire anemone *Actinodendron plumosum* is native to the South Pacific and produces significant local pain. One death occurred in the Virgin Islands following envenomation from an unknown species described as a "white anemone with blue tips." The onset of hepatic and renal failure was rapid and required transplantation, after which the patient died.⁶⁵ Nonfatal elevation of hepatic enzyme concentrations following anemone sting also is reported.¹⁷

Diagnostic Testing. Laboratory evaluation may be warranted in patients suffering systemic toxicity following Cnidaria

envenomation. Serial measurement of serum cardiac markers should be obtained from victims of Irukandji stings or others with consequential cardiovascular toxicity. Following severe stings from a variety of Cnidaria, urinalysis, hematocrit, and serum creatinine measurements should be considered to detect the presence of hemolysis and subsequent kidney injury. Chest radiography is indicated for complaints of dyspnea or abnormalities in oxygenation. Venom assays are not available, and serum antibody titers are not clinically useful.

Management. Initial interventions after Cnidaria envenomation are directed toward stabilization of cardiopulmonary abnormalities in cases of severe envenomation. Secondary measures are directed toward the prevention of further nematocyst discharge, which could intensify pain and enhance toxicity. Many topical therapies have been used for this purpose, including sea water, vinegar, a commercial solution known as Stingose, methylated spirits, ethanol, isopropyl alcohol, dilute ammonium hydroxide, urine, sodium bicarbonate, papain, shaving cream, and sand.

Vinegar is a common first-line treatment for topical application following Cnidaria stings. In vitro trials with *C. fleckeri* tentacles demonstrate complete irreversible inhibition of nematocyst discharge following a 30-second application.⁷¹ Additional study findings include massive nematocyst discharge with application of urine or ethanol, and no effect on discharge with use of sodium bicarbonate. Follow-up in vivo experiments demonstrate that vinegar is effective for other Cubozoa, including Morbakka (large Cubozoan in Australia),⁵¹ *Carybdea rastoni*,⁵⁴ and *C. barnesi*.⁵⁵ Although massive nematocyst discharge occurs when vinegar is applied to *C. capillata* tentacles in vitro, clinical exacerbation following this treatment is not reported in humans.⁵⁰ Massive discharge also occurs with *C. quinquecirrha*.⁵⁸ A smaller degree of discharge (30%) occurs with *P. physalis*,⁵⁸ whereas nematocysts of *P. utriculus* are unaffected by application of vinegar.⁷¹

Stingose is a commercially available product designed to counteract venom of insects, bees, stinging plants, and marine stingers. It is an aqueous solution of 20% aluminum sulfate and 1.1% surfactant. Its purported mechanism of action is denaturing of proteins and long-chain polysaccharides via interactions with the Al^{3+} ion, as well as osmotic removal of venom. A human volunteer trial involving stings from live tentacles of *C. fleckeri* demonstrated pain relief within 5 seconds of Stingose application.⁷³ Similar results were achieved following treatment of stings from *C. quinquecirrha*. Further investigation involved beachside evaluation of 17 *C. fleckeri* and 150 *P. utriculus* sting victims treated with Stingose immediately following injury. All victims reported rapid relief. However, placebo or alternative therapies were not used in this case series. The efficacy of treatment with vinegar, Stingose, methylated spirits, and salt water was measured in human volunteers following forearm application of *P. physalis* tentacles.¹⁴⁷ Vinegar demonstrated superior pain control compared with Stingose, whereas methylated spirits increased pain. The study assessed pain relief only and did not investigate the effects of the treatments on nematocyst discharge or systemic toxicity. A small volunteer study utilizing topical lidocaine reported successful treatment of stings via topical analgesia and reduced nematocyst discharge.¹³

In many cases the identity of the “jellyfish” causing injury is unknown. In those cases, therapy must be guided by geographic location. In the United States, where *P. physalis* and *C. quinquecirrha* are of greatest consequence, sea water should be used to aid in tentacle removal given that vinegar enhances nematocyst discharge in those species. In the Indo-Pacific region, where *C. fleckeri* and *C. barnesi* are of greatest concern, vinegar application confers greater advantage. Following a 30-second application, adherent tentacles must be carefully removed. This can be accomplished with a gloved or towel-covered hand, or with sand and gentle scraping with a credit card or other blunt, straight-edged tool.

In a nonrandomized trial, ice packs provided rapid, effective relief for patients with mild to moderate pain from Cnidaria stings in Australia.⁴⁷ Patients with severe pain were less likely to benefit from ice packs. Many Cnidaria venoms are heat labile and may be neutralized at 122°F (50°C) for 20 minutes leading some clinicians to recommend treating stings with hot water immersion (HWI). However, availability of hot water at the beach and the high temperature needed to neutralize venom limits implementation of this therapy. Some authors suggest that the use of heat is not only ineffective for venom neutralization, but that it also increases pain.¹⁸ However, recent controlled trials designed to address this controversy highlight the efficacy of HWI in lieu of cold packs for the treatment of stings from *Carybdea alata* and *Physalia* spp.^{58,91,107,142,152,161} This finding may relate more to gate control theory of pain and modulation of pain signals rather than venom destruction. HWI therapy for treatment of *C. fleckeri* stings has not been rigorously evaluated.

Pressure immobilization bandaging is a technique that applies sufficient pressure to a wound to impede lymphatic drainage and prevent the entrance of venom into systemic circulation. Its application for snakebites is commonplace outside the United States, while its role following Cnidaria stings has sparked controversy. Given the rapid onset of symptoms, the utility of a technique that impedes lymphatic drainage is unlikely to provide benefit. Although the technique would be used only after tentacle removal, some microscopic nematocysts remain adherent to the skin after visible tentacles are removed. In vitro data investigating the effect of pressure on discharged nematocysts demonstrate not only that discharged nematocysts still contain venom, but that applying pressure forces more venom down the hollow tube.¹¹² This finding is correlated clinically as patients can deteriorate following pressure immobilization bandaging.⁵⁷ Given the lack of evidence suggesting benefit, coupled with clear in vitro evidence of increased venom delivery with this technique, it should not be implemented for treatment of Cnidaria stings.

Box jellyfish antivenom is sheep-derived whole IgG raised against the “milked” venom of *C. fleckeri*. It has been

available in Australia since 1970. Combining *C. fleckeri* venom with box jellyfish antivenom prior to injection into pigs prevents all toxicity.¹⁴³ An isolated chick muscle experiment demonstrates that box jellyfish antivenom prevents the neurotoxicity and myotoxicity from *C. fleckeri* following pretreatment; however, there is no “rescue effect in this research.”¹¹³ Given that antivenom in humans is always used as a rescue therapy, the research raises concerns regarding efficacy in the clinical setting. Pretreatment of rats with box jellyfish antivenom prevented cardiovascular collapse in 40%, but did not blunt the initial hypertensive effect.¹¹⁴ In vitro data demonstrate that box jellyfish antivenom neutralizes the dermatonecrotic, hemolytic, and lethal fractions of venom from *Chiropsalmus* spp; however, the venom of *P. physalis* and *C. quinquecirrha* were not neutralized.¹⁰ Other in vitro and in vivo data demonstrate incomplete neutralization of *Chiropsalmus* spp venom.^{10,113}

There are no controlled studies in humans evaluating the efficacy of box jellyfish antivenom in the treatment of *C. fleckeri* envenomations, nor is there convincing evidence that its administration has saved human lives. Despite the frequency of hospital visits for stings from *C. fleckeri* in Australia, the use of box jellyfish antivenom is rare.⁴² Evidence for its efficacy stems from case reports suggesting that pain abates rapidly after administration.^{15,156} Although box jellyfish antivenom may improve pain control, patients still may require parenteral opioids for analgesia following antivenom administration.¹¹ Significant morbidity and mortality still occur despite antivenom use.^{41,92,136} Case reports of box jellyfish antivenom use for *C. barnesi* stings demonstrate no apparent benefit.⁴⁹

Many serious stings occur in the Northern Territory of Australia, where stinger nets are not commonly used. Distance from medical care limits the ability to obtain antivenom in a timely fashion.⁴² Although box jellyfish antivenom can be administered by paramedics via intramuscular (IM) injection,⁵⁷ poor IM absorption and incomplete venom neutralization with antivenoms, as well as delayed peak serum concentrations, limit the utility of this approach.¹²¹ The amount of antivenom required to neutralize twice the lethal dose in humans is estimated at 12 vials.⁴² The manufacturer recommends treating initially with one ampule intravenously (IV) diluted 1:10 with saline or three undiluted ampules (1.5–4 mL each) IM at three separate sites, if IV access is unavailable. Some authors who have treated multiple patients with antivenom suggest treating coma, dysrhythmia, or respiratory depression with one ampule IV, titrating up to three ampules with continuation of CPR in patients with refractory dysrhythmias until a total of six ampules have been administered.¹⁰⁹ For less serious envenomations, clinicians may consider administering one ampule if ice packs and parenteral analgesia prove ineffective.¹⁰⁹ Serious adverse events or delayed sequelae following the use of IV antivenom are uncommon, although allergic reactions are a consideration.¹³⁷

Verapamil was evaluated as a treatment for *C. fleckeri* stings based on evidence that Ca^{2+} entry into cells represents an important mechanism of toxicity. One animal model demonstrated synergy with use of verapamil in combination with box jellyfish antivenom,²⁸ whereas another showed verapamil pretreatment as well as rescue prolonged survival.²¹ This is in contrast to other models demonstrating that verapamil negates the benefits of antivenom¹¹⁴ and increases mortality.¹⁴³ Verapamil administration to animals with *C. quinquecirrha* envenomation demonstrated no benefit.¹⁰⁴ Interestingly, addition of magnesium to antivenom for treatment of *C. fleckeri* envenomation in rats prevented cardiovascular collapse in 100%, suggesting that magnesium may have a role in the treatment of stings from this species.¹¹⁴ Given that animal data are inconsistent with regard to verapamil and that hypotension may develop with severe envenomation, use of calcium channel blockers is not currently recommended for treatment of *C. fleckeri* stings.

Treatment for Irukandji syndrome should focus on analgesia and blood pressure control. Several modalities for control of severe hypertension have been suggested and include phentolamine, IV magnesium sulfate, and nitroglycerin.^{40,53} Dosing guidelines and efficacy following magnesium infusion for this indication are not established. Whereas hypotension may occur in late stages of toxicity, clinicians should also consider short-acting titratable agents such as esmolol, nitroprusside, or nicardipine.

Mollusca

The phylum Mollusca (Latin mollis meaning soft) includes the classes Cephalopoda (octopus, squid, and cuttlefish) and Gastropoda (cone snails). Cephalopod species of toxicologic concern are limited to the blue-ringed octopus *Hapalochlaena maculosa* and the greater blue-ringed octopus *Hapalochlaena lunulata*. The blue-ringed and greater blue-ringed octopi are found in the Indo-Pacific region, primarily in Australian waters (Fig. 119–2). Of the 400 species of cone snails that belong to the genus *Conus*, 18 are implicated in human envenomations.

FIGURE 119–2 The blue ringed octopus, *Hapalochlaena maculosa*. (Used with permission of Dr. Roy Caldwell, Professor of Integrative Biology, University of California, Berkeley.)

History and Epidemiology. The blue-ringed octopus normally displays a yellow-brown color, but develops iridescent blue rings when threatened. The species is not aggressive and only bites humans when handled. A 1983 review of reported octopus envenomations uncovered a total of 14 cases, all of which occurred in Australia.¹⁴⁹ There were two deaths⁶² and four serious envenomations. Other reviews suggest that up to seven deaths may have occurred prior to 1969, some outside Australia⁴⁵

Estimates of reported cone snail envenomations suggest only 15 human deaths have occurred worldwide.⁴⁸ *Conus geographicus* (fish hunting cone) is the most common species implicated, although *Conus textile* may also cause death in humans. Cone snails predominantly inhabit the Indo-Pacific, including all parts of Australia, New Guinea, Solomon Islands, and the Philippines. Two deaths from *C. geographicus* occurred in Guam.⁸⁵

Pathophysiology. The salivary gland of the blue ringed octopus secretes a toxin originally designated maculotoxin and later identified as tetrodotoxin.¹³¹ The beak of the octopus creates small punctures in human skin through which venom is introduced. Tetrodotoxin blocks Na^+ conductance in neurons, leading to paralysis. Venom also contains serotonin (5-HT), hyaluronidase, tyramine, histamine, tryptamine, octopine, taurine, acetylcholine, and dopamine.¹³⁸ Rabbits subjected to bites develop rapid flaccid paralysis without cardiotoxicity and die from asphyxia. Other animal models using venom gland extract demonstrate rapid onset of respiratory muscle paralysis and severe hypotension.⁶⁰ Death occurs despite artificial respiration and results from hypotension.

Cone snails have a hollow proboscis that contains a tooth bathed in venom. Envenomations occur when the shells are handled. The proboscis can extend the length of its shell, thereby envenomating the hand of someone touching the opposite end of the shell. Any *Conus* species contains approximately 100 peptides or conotoxins in its venom along with hyaluronidases that aid in local tissue breakdown.¹⁴⁸ Targets include voltage- and ligand-gated ion channels as well as G-protein-linked receptors (Table 119–2).^{84,110,141} Many of these peptides are used extensively in laboratory research for their ability to selectively target a variety of specific Ca^{2+} channel subtypes. Venom from *Conus imperialis* (worm hunter) contains a substantial amount of 5-HT, a component not found in any other *Conus* venom tested thus far.⁹⁹ This species also contains a vasopressinlike peptide.¹⁰⁶ The neuropeptide omega-conotoxin, isolated from *Conus magnus*, is valued for its antinociceptive properties that arise from blockade of the N-type voltage-sensitive Ca^{2+} channel in spinal cord afferents.⁹⁸ The Food and Drug Administration approved ziconotide (Prialt, Elan Pharmaceuticals) in 2004 for intrathecal (IT) infusion in patients with severe chronic pain that require IT therapy, and in whom other treatment modalities such as IT morphine are not tolerated or ineffective. Patients reported modest improvements in pain with long-term treatment.¹⁵¹ Frequent side effects such as dizziness, nausea, confusion, and memory impairment limit the broad application of this therapy.

TABLE 119–2. *Conus* Peptide Targets

Receptor Type	Peptide	Mechanism
<i>Ligand-gated ion channels</i>		
Nicotinic	α -Conotoxin	Competitive antagonism
	M1	Neuromuscular junction
	M2	Neuronal receptors
5-HT ₃	σ -Conotoxin	Noncompetitive antagonism
NMDA	Conantokins	Inhibits conductance
<i>Voltage-gated ion channels</i>		
Ca ²⁺	ω -Conotoxin	Channel blockade
Na ⁺	μ -Conotoxin	Channel blockade
	δ -Conotoxin	Delayed channel activation
K ⁺	κ -Conotoxin	Channel blockade
<i>G-protein linked</i>		
Vasopressin receptor	Conopressin-G	Receptor agonism
Neurotensin receptor	Contulakin-G	Receptor agonism

Clinical Manifestations. The blue-ringed octopus creates one or two puncture wounds with its chitinous jaws, inflicting only minor discomfort. A wheal may develop with erythema, tenderness, and pruritus. Tetrodotoxin exerts a curarelike effect characterized by paralysis without depressing mental status. Symptoms include perioral and intraoral paresthesias, diplopia, aphonia, dysphagia, ataxia, weakness, nausea, vomiting, flaccid muscle paralysis, respiratory failure, and death. Detailed case reports describe rapid onset of symptoms.^{32,149} Complete paralysis requiring intubation with findings of fixed and dilated pupils is followed within 24 to 48 hours by near-complete recovery of neuromuscular function. In one reported death, a young man placed the octopus on his shoulder. He subsequently noted a small puncture wound, developed dry mouth, dyspnea, inability to swallow, and became apneic. Asystole occurred 30 minutes after arrival at the hospital despite mechanical ventilation.⁶² Another similar bite resulted in symptom onset at 10 minutes, followed by death at 90 minutes, despite bystander CPR.¹³⁸ With less severe envenomations, cerebellar signs may arise without paralysis. Near-total paralysis with intact mentation resolving over 24 hours is described in humans.¹³⁸

Cone snail envenomation results from careless handling of the animal or rummaging through sand. Cone snails are nocturnal feeders, so they may present more of a hazard to night divers. Localized symptoms range from a slight sting to excruciating pain, tissue ischemia, cyanosis, and numbness. Systemic symptoms include weakness, diaphoresis, diplopia, blurred vision, aphonia, dysphagia, generalized muscle paralysis, respiratory failure, cardiovascular collapse, and coma. Death is rapid and occurs within 2 hours. Based on military medical records of more than 30 cases predating 1970, the mortality rate approaches 25%, with *C. geographicus* causing the most deaths.⁸⁵ Other estimates suggest that, without medical care, mortality may reach 70%.¹⁶⁰ Given the rarity of severe human envenomations from cone snails, the manner of death, whether purely from respiratory insufficiency or direct cardiovascular toxicity, remains unknown.

Diagnostic Testing. Laboratory testing following envenomation from octopi or cone snails should be directed by clinical findings. Although not a widely available assay, tetrodotoxin can be detected in the urine or serum using high-performance liquid chromatography with subsequent fluorescence detection.¹⁰⁸

Management. Primary interventions include maintenance of airway, breathing, and circulation. Some authors recommend hot water (113°–122°F, 45°–50°C,) following cone snail stings for pain relief.⁸⁵ Unlike Cnidaria envenomations, where nematocysts full of venom can persist on the skin and lead to continued venom delivery, stings from the octopus and cone snail mirror those of snakebites, where venom delivery is an immediate and finite event. Therefore, pressure immobilization bandaging may blunt toxin distribution by decreasing lymphatic spread.⁴⁸ Additional measures include local wound care and tetanus prophylaxis. Antivenom is not available for octopus or cone snail venoms.

Echinodermata, Annelida, and Porifera

The Echinodermata phylum includes sea stars, brittle stars, sea urchins, sand dollars, and sea cucumbers. Annelida are segmented worms that include the Polychaetae family of bristle worms. Sponges are classified in the Porifera phylum. One feature that all three phyla share is the passive envenomation of people who mistakenly handle or step on the animals. Most stings from these creatures are mild.

History and Epidemiology. Echinoderms, annelids, and sponges are ubiquitous ocean inhabitants. The crown-of-thorns *Acanthaster planci* is found in the warmest waters of Polynesia to the Red Sea and is a particularly venomous species because of its sharp spines that easily puncture human skin. Sea urchins inhabit all oceans of the world. Bristle worms such

as *Hermodice carunculata* typically inhabit tropical waters such as those of Florida and the Caribbean. However, some species thrive in the frigid waters of Antarctica. The fire sponge *Tedania ignis* is a brilliant yellow-orange sponge identified in large numbers off the coast of Hawaii and in the Florida Keys. Other common American sponges are *Neofibularia nolitangere* (poison-bun sponge or touch-me-not sponge) and *Microciona prolifera* (red sponge). *Neofibularia mordens* (Australian stinging sponge) is a common Southern Australian variety. In the Mediterranean, sponges are often colonized with sea anemones that may inflict severe stings.¹⁶

Pathophysiology. Sea urchins are covered in spines and pedicellariae. The pedicellariae are pincerlike appendages used for feeding, cleaning, and defense. They generally contain more venom than the spines and are more difficult to remove from wounds. Urchins laden with pedicellariae can evoke more severe stings than urchins with less pedicellariae. Venom contained within the spines consists of steroid glycosides, serotonin, hemolysin, protease, and acetylcholinelike substances. Some species harbor neurotoxins. The most venomous are species of *Diadema*, *Echinothrix*, and *Asthenosoma*. Sea stars are less noxious because they generally have short, blunt spiny projections. The crown-of-thorns is the exception with its longer, sharp spines containing toxic saponins with hemolytic and anticoagulant effects as well as histaminelike substances.¹³⁹ Sea cucumbers excrete holothurin, a sulfated triterpenoid oligoglycoside, from the anus (organs of Cuvier) as a defense. The toxin inhibits neural conduction in fish, leading to paralysis. Some sea cucumbers eat Cnidaria and subsequently secrete their venom.

Bristle worms have many parapodia that have the appearance, but not the function, of legs. Several bristles extend from each parapodium giving the family (Polychaeta) its name (poly means many, chaetae means bristles). The bristles may penetrate human skin, leading to envenomation with an unknown substance.

Sponges have an elastic skeleton with spicules of silicon dioxide or calcium carbonate. They attach to the sea floor or coral beds. Toxins include halitoxin, odadaic acid, and subcritine, the nature of which is uncertain.²² Dried sponges are nontoxic; however, on rewetting they may produce toxicity even after several years.¹³⁴

Clinical Manifestations. Most injuries from sea urchins are caused by inadvertently stepping on the spines or attempting to handle the animal. An intense burning with local tissue reaction occurs, including edema and erythema. Rarely, with multiple punctures, lightheadedness, numbness, paralysis, bronchospasm, and hypotension may reportedly occur, although this is not documented in the peer-reviewed medical literature.³ Reports of death are not well substantiated. The Pacific urchin *Tripneustes* has a neurotoxin with a predilection for cranial nerves.¹⁶ Mild elevations of hepatic enzymes are reported in one patient with foot cellulitis from an urchin sting.¹⁵⁹ Small cuts on the skin from handling starfish may allow venom to penetrate, leading to contact dermatitis. The crown-of-thorns may cause severe pain, nausea, vomiting, and muscular paralysis.⁹⁷ Cutaneous, scleral, or corneal exposure to sea cucumbers triggers contact dermatitis, intense corneal inflammation, and even blindness. Bristle worms are shrouded with bristles that can produce a reddened urticarial rash. Symptoms typically are mild and resolve over several hours to days.

Contact with the fire sponge, poison-bun sponge, or red-moss sponge causes erythema, papules, vesicles, and bullae that generally subside within 3 to 7 days. Victims may develop fever, chills, and muscle cramps. Skin desquamation occurs at 10 days to 2 months,⁴ with chronic skin changes lasting several months.²² Erythema multiforme and anaphylaxis are uncommon complications associated with *Neofibularia* spp exposure.¹⁶ Contact with sponges that are colonized with Cnidaria can lead to dermatitis with skin necrosis, referred to as sponge diver's disease.

Management. The primary objective following envenomation from sea urchins and crown-of-thorns starfish is analgesia. Submersion of the affected extremity in hot water (105°–115°F, 40.6°–46.1°C) and administration of oral analgesics often is sufficient.^{48,97} Puncture wounds require radiographic evaluation to locate potential foreign bodies. Spines frequently crumble with attempted extraction. Intraarticular spines necessitate surgical removal. Decisions regarding spines in other locations should be influenced by ease of removal, presence of infection, and persistent pain. Tetanus immune status must be addressed. Decisions regarding antibiotic prophylaxis should be based on degree of injury and patient factors such as diabetes or other comorbidities. Although most infections likely are secondary to human skin flora, marine flora such as *Mycobacterium marinum* and *Vibrio parahaemolyticus* are potential wound contaminants. Treatment of sponge exposures usually requires only removal of spicules using adhesive tape or the edge of a credit card. Antihistamines and topical corticosteroids often provide no relief from stinging sponges.²²

VERTEBRATES

Snakes

Sea snakes are members of the class Reptilia and are divided into two subfamilies: Hydrophiinae and Laticaudinae. They are close relatives of the cobra and krait. Length typically does not exceed 1 m. Their tails are flattened, and their bodies often are brightly colored. Distinction from eels is made by the presence of scales and the absence of fins and gills. All 52 species of sea snakes are venomous and at least six species are implicated in human fatalities. The most common species cited in human envenomation are *Enhydrina schistosa*, the beaked sea snake, and *Pelamis platurus*, the yellow-bellied sea

snake.

History and Epidemiology. Sea snakes are common to the tropical and temperate Indian and Pacific Oceans, but they are also found along the eastern Pacific Coast of Central and South America and the Gulf of California. In the eastern Pacific region, the yellow-bellied sea snake is the only species known. There are no sea snakes in the Atlantic Ocean. The majority of envenomations occur along the coasts of Southeast Asia, the Persian Gulf, and the Malay Archipelago (Malaysia). Snakes tend to inhabit the turbid coastlines and deeper reefs of these regions.

The true incidence of sea snake envenomation is unknown because many bites are not recorded. Worldwide the number of deaths per year may approach 150, with an overall mortality rate estimated at 3%.⁴⁸ In a review of 120 documented bites, 51.7% of victims were fishermen handling nets.¹¹⁸ The remainder of victims were wading or swimming along the coastline. In a review of 101 bites occurring from 1957 to 1964 in Northwest Malaysia, more than 50% of bites were from the beaked sea snake, including seven of the eight fatal bites in that series, bringing the mortality to 8% prior to the availability of antivenom.¹²⁰ However, 31 “dry bites” were excluded, suggesting that the overall mortality is somewhat lower. Among the 20% of patients in that series suffering “serious envenomation,” half died despite supportive care. A follow-up series of patients after the introduction of antivenom described 2 deaths out of 11 “serious envenomations,” suggesting a decreased mortality resulting from this intervention. These were all retrospective reviews of published or personally communicated cases.

Pathophysiology. All sea snakes have small front fangs. Their venom is neurotoxic, myotoxic, nephrotoxic, and hemolytic. Known components of the venom include acetylcholinesterase, hyaluronidase, leucine aminopeptidase, 5'-nucleotidase, phosphodiesterase, and phospholipase A. The neurotoxin is a highly stable 6000-to 8000-Da protein similar to that of cobra and krait venom. In mice, beaked sea snake venom is four to five times more potent than cobra venom based on a $\mu\text{g/kg}$ ratio; however, cobra venom yield is greater.³¹ Venom homology exists across many species.⁷⁷ The neurotoxin targets postsynaptic acetylcholine (ACh) receptors creating a blockade at the neuromuscular junction.¹⁴⁰ Presynaptic effects include initial enhanced ACh release and subsequent inhibition of ACh release.^{103,120,150} In vitro research confirms direct nephrotoxicity of crude venom and may partially explain the nephrotoxicity described clinically.¹³⁰ Rhabdomyolysis likely contributes to this clinical finding.

Clinical Manifestations. Sea snakes generally are docile, except when provoked, or during the mating season. Bites typically are painless or inflict minimal discomfort. Between one and four fang marks are common; however, up to 20 fang marks are possible as a result of multiple bites. The diagnosis can be obscured because victims may not associate the slight prick following the bite with later onset of ascending paralysis. Symptoms may progress within minutes, although a delay of up to 6 hours is possible. Neurotoxin-induced paralysis occurs in conjunction with muscle destruction stemming from myotoxic fractions. Painful muscular rigidity and myoglobinuria are hallmarks of sea snake myotoxicity. Myoglobinuria develops between 30 minutes and 8 hours after the bite. Other classic symptoms include ascending flaccid paralysis, dysphagia, trismus, ptosis, aphonia, nausea, vomiting, fasciculations, and ultimately respiratory insufficiency, seizures, and coma.

Diagnostic Testing. Laboratory diagnostics are directed toward identifying hemolysis, myonecrosis, hyperkalemia, and acute kidney injury. Serum electrolytes, creatinine, and creatine phosphokinase, as well as hematocrit and urinalysis, should be obtained. Elevated concentrations of hepatic enzymes may indicate severe envenomation. Serial measurement of these parameters is recommended.

Management. Prehospital management of sea snakebites mirrors treatment of terrestrial snakebites (Chap.122) and includes immobilization of the extremity and consideration of a pressure immobilization bandage to impede lymphatic drainage. Currently no data regarding the efficacy of this technique for sea snake envenomations are available. Tourniquets that impede venous or arterial flow are not recommended and may be detrimental. Airway and respiratory effort require close monitoring because paralysis can develop rapidly.

The most commonly used antivenoms for sea snakes are equine IgG Fab fragments produced using the venom of beaked sea snake (*E. schistosa*) or terrestrial tiger snake (*Notechis scutatus*) (Table 119–3). In vitro experiments demonstrate that sea snake antivenom is effective for neutralizing all species of sea snakes tested (*Praescutata viperina* in Thailand, *P. platurus* in Central America, *Laticauda semifasciata* in the Philippines, *Laticauda laticaudata* in Japan, *Hydrophis cyanocinctus*, *Lapemis hardwickii*).¹⁴⁶ Optimal neutralization occurs within the subfamily Hydrophiinae, which contains *E. schistosa*; however, effective neutralization is demonstrated within the subfamily Laticaudinae. Terrestrial tiger snake antivenom also can neutralize sea snake venom in vitro. Based on the volume of antivenom required, tiger snake antivenom was superior for neutralization of all sea snake venoms tested except that of the beaked sea snake, for which sea snake antivenom was more effective.⁷ This finding is expected because sea snake antivenom is raised against beaked sea snake venom. In contrast to volume comparisons, measurements of unit dosing demonstrate sea snake antivenom is more effective for all venoms tested. Another in vitro study comparing tiger snake and sea snake antivenom against venom *E. schistosa* demonstrated tiger snake antivenom was 10 times more effective in terms of milligram of venom neutralized per milliliter of antivenom.¹⁰² In the same study, the use of 17 different types of elapid antivenom resulted in poor neutralization of beaked sea snake venom.

TABLE 119–3. Antivenoms

Organism	Derivation	Concentration
<i>Box jellyfish</i> <i>C. fleckeri</i>	Ovine, whole IgG	20,000 Units/ampule
<i>Sea snake</i> <i>E. schistose</i> (beaked sea snake)	Equine, IgG Fab	1000 Units/ampule
<i>N. scutatus</i> (terrestrial tiger snake)	Equine, IgG Fab	3000 Units/ampule
<i>Stonefish</i> <i>S. trachynis</i>	Equine, IgG Fab	2000 Units/ampule

CSL = Commonwealth Serum Laboratories, Melbourne, Australia manufacture these antivenom.

In rescue experiments with mice using 11 sea snake venoms and 4 different antivenoms (*E. schistosa*, *E. schistosa*-*N. scutatus*, *N. scutatus*, and polyvalent sea snake *L. hardwickii*, *L. semifasciata*, *H. cyanocinctus*), tiger snake antivenom was superior to all others with respect to volume amount required to prevent death.^{2,8,64} Another finding of the study was improved efficacy with early administration of antivenom.

No controlled human trials have evaluated the efficacy of sea snake antivenom, although case reports suggest improved outcomes and more rapid recovery with its use.^{101,120} Anecdotal experience in Malaysia using sea snake antivenom suggests slow recovery from myalgias and weakness over 48 hours, compared with resolution over 2 weeks without antivenom (two cases, one control).¹¹⁹

Based on in vitro and in vivo research, selection of the optimal antivenom for treatment of sea snakebites is unclear. Both sea snake and tiger snake antivenom are effective in neutralizing a wide variety of sea snake venoms. Therefore, the most readily available antivenom should be used when needed. Commonwealth Serum Laboratories manufactures both monovalent sea snake and tiger snake antivenom for use in Australia. However, there is limited distribution to aquariums and zoos outside Australia. The manufacturer's guidelines for use of monovalent sea snake antivenom recommend administration of one ampule (1000 units) for systemic symptoms. However, because symptoms may be delayed and early administration is more likely to result in venom neutralization, any evidence of envenomation should prompt the administration of antivenom. The antivenom requires a 1:10 dilution with 0.9% sodium chloride solution followed by administered IV over 30 minutes. A 1:5 dilution can be used for small children. Skin testing is not recommended. Epinephrine and antihistamines should be readily available. No upper limit is suggested for the number of vials to administer, although larger amounts are more likely to result in serum sickness. Patients have received up to 7000 units without adverse effect directly attributable to the antivenom.¹⁰¹ One ampule (3000 units) of tiger snake antivenom can be used as an alternative if sea snake antivenom is unavailable. Other treatments should focus on wound care, tetanus prophylaxis, analgesia, and fluid administration to minimize nephrotoxicity from myoglobinuria.

Fish

Stingrays are members of the class Chondrichthyes (order Rajiformes: skates and rays). Families include Dasyatidae (whip ray or sting ray), Urolophidae (round ray), Myliobatidae (batfish or eagle ray), Gymnuridae (butterfly ray), and Potamotrygonidae (river ray, freshwater).

Spiny fish of the family Scorpaenidae include a variety of venomous creatures (Table 119–4). Fish of the genus *Pterois* are commonly called lionfish (*P. volitans* and *P. lunulata*). Stonefish are grouped under the genus *Synanceja* and include *S. trachynis* (Australian estuarine stonefish), *S. horrida* (Indian stonefish), and *S. verrucosa* (reef stonefish). They are unattractively disguised to blend in with the rocky sea bottom (Fig. 119–3). Scorpionfish have a similar appearance and belong to the genus *Scorpaena* (eg, *S. guttata*: California sculpin). Other Scorpaenidae include *Notesthes robusta* (bullrout) and *Gymnapistes marmoratus* (cobbler). The European weeverfish produce toxicity similar to members of Scorpaenidae and are classified under the family Trachinidae. This includes *Trachinus vipera* (lesser weever) and *Trachinus draco* (greater weever, aka adderpike, stingfish, seacat). These bottom dwellers are smaller and have fewer spines than Scorpaenidae and are much less ghoulish in appearance. Catfish also may envenomate humans. Although most live in freshwater, marine catfish such as *Plotosus lineatus* can inflict injury. Other venomous spiny fish include rabbitfish, stargazers, toadfish, ratfish, and even some sharks that have spines on their dorsal fins (Port Jackson shark, dogfish shark).

TABLE 119–4. Spiny Fish

<i>Latin Name</i>	<i>Common Name</i>	<i>Habitat</i>
Scorpaenidae family		
<i>Pterois</i>		
<i>P. volitans</i>	Lionfish (also zebrafish, turkeyfish, or red firefish)	Indo-Pacific region, coast of Florida to North Carolina (nonnative to US coast)
<i>P. lunulata</i>	Lionfish or butterfly cod	
<i>Synanceja</i>		
<i>S. trachynis</i>	Australian estuarine stonefish	Indo-Pacific region (Pacific and Indian Oceans)
<i>S. horrida</i>	Indian stonefish	
<i>S. verrucosa</i>	Reef stonefish	
<i>Scorpaena</i>		
<i>S. cardinalis</i>	Red rock cod, scorpionfish	Coast of Australia
<i>S. guttata</i>	California sculpin, scorpionfish	Coast of California
<i>Notesthes robusta</i>	Bullrout	Coast of Australia
<i>Gymnapistes marmoratus</i>	Cobbler	Coast of Australia
Trachinidae family		
<i>Trachinus</i>		
<i>T. vipera</i>	Lesser weeverfish	Coasts of Great Britain to Northwest Africa, throughout
<i>T. draco</i>	Greater weeverfish (also adderpike, stingfish, or seacat)	Mediterranean and Black Seas

FIGURE 119-3 The stonefish, *Synanceja* spp. Note the stinging spines on the close-up. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

History and Epidemiology. There are 11 different species of stingrays in US coastal waters (seven in the Atlantic, four in the Pacific). In the southeastern United States, *Dasyatis americana* is a common inhabitant. *Urolophus halleri* is the most common species on the western coast of the United States. Some estimates suggest 1500 to 2000 stingray injuries occur yearly in the United States. Most envenomations occur when the animal is inadvertently stepped on. In one review a total of 17 fatalities resulting from trunk wounds, hemorrhage, or tetanus were identified worldwide.⁴⁸ Another review of 603 cases of stingray injuries identified two deaths resulting from intraabdominal trauma.¹²⁴

Three populations are at highest risk for spiny fish envenomation: fishermen sorting the catch from nets, waders, and aquarium enthusiasts. Only five deaths from Scorpaenidae have been reported; all resulted from stonefish and are poorly documented.^{39,48} No deaths from stonefish are reported in Australia, a country where they are commonly found in coastal waters.⁴² The incidence of weeverfish stings is unknown, but they are a common occurrence in the summertime among Italian coastal towns.^{30,133} Scorpaenidae inhabit waters throughout the tropical and temperate oceans. They exist as far north as the Gulf of Oman and Southern Japan and extend south beyond New Zealand. In the United States, Scorpaenidae stings occur in the Florida Keys, in the Gulf of Mexico, off the coast of California, and in Hawaii. Lionfish (genus *Pterois*) (Fig. 119-4) are common to home aquariums and account for most poison center calls involving spiny fish envenomation in the United States. The bullrout inhabits the eastern coast of Australia, along with the cobbler, which is found only in Australia. Weeverfish inhabit shallow temperate waters with sandy or muddy bottoms in the eastern Atlantic and Mediterranean, including the European Coast extending to the southern tip of Norway.²⁹ The marine catfish lives in the tropical Indo-Pacific waters.

FIGURE 119-4 (A) The lionfish, *Pterois volitans*. (B) This patient's hand was envenomated by his pet lionfish while cleaning his aquarium. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Pathophysiology. Tapered, bilaterally retroserrated spines covered by an integumentary sheath emanate from the stingray tail. The ventrolateral groove contains venom glands that saturate the spine with venom and mucus. The venom contains several amino acids, serotonin, 5'-nucleotidase, and phosphodiesterase.⁴ In animal models, venom induces local vasoconstriction, bradydysrhythmias, atrioventricular nodal block, subendocardial ischemia, seizures, coma, cardiovascular collapse, and death.^{3,124} A rabbit model demonstrates initial vasodilation followed by vasoconstriction and cardiac standstill, suggesting a direct cardiac effect.¹²⁵ Wound specimens reveal necrotic muscle and neutrophilic infiltrates.⁶ Other reports show central hemorrhagic necrosis with surrounding lymphoid and eosinophilic infiltrates indicating an immune-mediated cause of delayed wound healing.⁶⁷

Scorpaenidae have 12 to 13 dorsal, 2 pelvic, and 3 anal spines that are covered with an integumentary sheath. Glands at the base contain 5 to 10 mg of venom each. Ornate pectoral fins are not venomous. Venom can remain stable for 24 to 48 hours after the fish dies.⁹⁶ Three main toxins have been isolated from various species of stonefish: stonustoxin (SNTX), verrucotoxin (VTX), and trachynilysin (TLY). SNTX, from *S. horrida*,⁶⁸ has two subunits, α and β (71,000 and 79,000 Da, respectively). It induces formation of hydrophilic pores in cell membranes.³³ Toxicity in animals includes hemolysis, local edema, vascular permeability, platelet aggregation, endothelium-dependent vasodilation, and hypotension. Decreased myocardial contractility occurs in rabbits.¹²⁸ Heating stonefish venom to 122°F (50°C) for 5 minutes prevents wound necrosis and hypotension in animal models.¹⁵³ VTX, isolated from *S. verrucosa*, shares homology with SNTX in that both block cardiac Ca^{2+} channels.⁶⁶ TLY, isolated from *S. trachynis*, is a 159-kDa protein that forms pores in cell membranes. It allows Ca^{2+} entry and causes Ca^{2+} -dependent release of ACh from nerve endings at motor end plates and increased catecholamine release.^{81,111,129} *S. trachynis* venom causes endothelium-dependent vasodilation and cardiovascular collapse

in rats, which appears to be mediated by muscarinic and adrenergic receptors.³⁴ Hemolysis is demonstrated in animals but does not occur in humans.⁸⁰ Other venoms of Scorpaenidae include hyaluronidase, proteinase, phosphodiesterase, alkaline phosphomonoesterase, arginine esterase, arginine amidinase, 5'-nucleotidase, acetylcholinesterase, and biogenic amines. Crude venom from *G. marmoratus*, *P. volitans*, and *S. trachynis* leads to increased intracellular Ca^{2+} and muscle contracture in vivo.³⁷ Toxins from other spiny fish include dracotoxin (*T. draco*), trachinine (*T. vipera*), and nocitoxin (*N. robusta*).³⁶ Effects mirror those of Scorpaenidae toxins.¹³²

Clinical Manifestations. Stepping on the body of a stingray causes a reflexive whip of the tail leading to wounds in the lower extremity. Intense pain out of proportion to the appearance of the wound is characteristic. Symptoms peak 30 to 90 minutes after injury and may persist for 48 hours. Local edema, cyanosis, erythema, and petechiae may follow rapidly and may lead to necrosis and ulceration. Systemic symptoms include weakness, nausea, vomiting, diarrhea, vertigo, headache, syncope, seizures, muscle cramps, fasciculations, hypotension, and dysrhythmias. Chest and abdominal wounds, as well as tetanus, have caused death.¹¹⁷

Stings from stonefish produce immediate, severe pain with rapid wound cyanosis and edema that may progress up the injured extremity. Pain reaches a maximum after 30 to 90 minutes and usually resolves over 6 to 12 hours, although pain may persist for days. Headache, vomiting, abdominal pain, delirium, seizures, limb paralysis, hypertension, respiratory distress, dysrhythmias, congestive heart failure, and hypotension characterize systemic toxicity.⁸³ Wound healing may require months.

A poison center case series from 1979 to 1988 identified 23 cases of *P. volitans* envenomation.¹⁴⁵ Reported symptoms included pain, swelling, nausea, numbness, joint pain, anxiety, headache, dizziness, and cellulitis. Another Poison Center series identified 51 Scorpaenidae stings (45 *P. pterois*, 6 *S. guttata*).⁷⁹ Intense pain was reported in 98%, extension of pain to the limb in 22%, swelling in 58%, and systemic signs (nausea, diaphoresis, dyspnea, chest pain, abdominal pain, weakness, hypotension, and syncope) in 13%. Thirteen percent of patients in the series developed wound infection; one patient's wound healing was delayed several weeks. Stings from weeverfish are similar to Scorpaenidae envenomation and rarely result in death.¹⁴ Injury from catfish stings is comparable to that of other stinging fish.⁴⁴

Management. Wounds inflicted by stingrays and spiny fish should be carefully examined for imbedded foreign material. Radiographs may uncover retained spines. Stingray wounds can be extensive and require surgical attention for vascular or tendonous disruption. Tetanus immune status should be addressed. Prophylactic antibiotics may decrease rates of wound infection.³⁸ In a series of 51 stings from *P. pterois* and *S. guttata*, 80% of patients had complete relief of local pain with hot water immersion.⁷⁹ Hot water produces similar relief for pain from weeverfish stings.¹²³ A review of 119 stingray envenomations demonstrates comparable efficacy with hot water immersion.³⁸ Although patients occasionally required a single dose of oral or parenteral analgesia, clinicians rarely prescribed analgesics upon discharge. In a human volunteer study in which subjects received a subcutaneous injection of stingray venom, severe pain developed immediately, and was alleviated with water heated to 122°F (50°C).¹²⁴ Pain increased with application of cold water. Local lidocaine infiltration provides an alternate modality for pain control.⁵⁹

Stonefish antivenom, an equine-derived IgG Fab fragment, is raised against the venom of *S. trachynis*. Each ampule contains 2000 units and neutralizes 20 mg venom. Between 1965 and 1981, antivenom was used in at least 267 cases.⁴² Anecdotal reports suggest it provides effective relief from pain.^{42,154} In a review of 26 documented cases in Australia where antivenom was administered IM, no acute adverse effects were identified.¹³⁷ Two of 15 patients who had follow-up visits suffered serum sickness. Rash may develop several days postinjection.¹⁵⁴ In vitro and in vivo research with the antivenom demonstrates neutralization of venom from *G. marmoratus*³⁵ and *P. volitans*³⁶; however, the application for human therapy remains untested.

The manufacturer recommends IM administration of stonefish antivenom, although IV administration may be considered. Administration is indicated for systemic toxicity or refractory pain. The number of puncture wounds guides therapy: one vial for one to two punctures, two vials for three to four punctures, and three vials for five or more punctures. Epinephrine and diphenhydramine should be readily available for treatment of anaphylactic reactions.

SUMMARY

- Fatalities from marine envenomations are rare. However, significant morbidity may result from bites and stings, including severe pain, retained foreign bodies, infection, respiratory compromise, hemodynamic instability, and a variety of other end organ toxicities.
- Special attention is required when treating envenomations inflicted by box jellyfish or sea snakes. These injuries are not uncommon and may result in serious harm or even death. Knowledge of the clinical manifestations and available antidotes may reduce morbidity.
- A thorough understanding of the mechanisms of toxicity and expected clinical course following envenomations from marine creatures will provide clinicians with the ability to manage these injuries effectively.

- Interventions should focus on patient comfort and recognition of potential complications.
- Hot water immersion (HWI) may provide adequate analgesia from a number of different species of Cnidaria, as well as stings from a variety of spiny fish.

120 MUSHROOMS

Lewis R. Goldfrank

The diversity of mushroom species is evident in our grocery stores, our restaurant menus, and our environment. The enhanced interest in mushrooms has led to experimentation by young and old—old citizens and our newest immigrants and our young children reaching for what might become an innocuous or a serious ingestion. Rigor in analyzing the possible ingestion is indispensable for physicians treating a patient who has ingested a mushroom of concern. This chapter offers general information of the most consequential toxicologic groups of mushrooms and emphasizes clinical diagnosis over mushroom identification.

EPIDEMIOLOGY

Unintentional ingestions of mushrooms particularly in children represent a small but relatively constant percentage of consultations requested from poison centers ([Chap. 136](#)). A summary of a quarter century of American Association of Poison Control Centers (AAPCC) data reveals that mushrooms represent less than 0.25% of the reported human exposures. Combined data accumulated by the AAPCC and the Mushroom Poisoning Registry of the North American Mycological Association indicates that approximately 5 patient exposures to toxic mushrooms per 100,000 persons occur per year. Some variations result from geographic and climatic conditions and mycologic habitats.¹²¹ Although the methods of analysis of patients with mushroom exposure have changed over the past 30 years, cumulative AAPCC data consistently demonstrate the relative benignity of the vast majority of exposures. The inability of most health care providers to correctly identify the ingested mushroom and the rarity of lethal outcomes are demonstrated by the accumulated data. In 75% to 95% of cases, the exact species was unidentified¹²¹ ([Chap. 136](#)). More than 50% of exposed individuals had no symptoms. Most patients were treated at home and rarely had major toxicity. During the 30 years covered by the AAPCC data, fewer than 100 patients died of their mushroom ingestion. Of the mushrooms associated with death, most were *Amanita* spp and several were hallucinogens, *Boletus* spp, gyromitrin-containing mushrooms, while others remained unidentified. All reported deaths occurred in adults. Those containing either hallucinogens or gastrointestinal (GI) toxins were the most common reported exposures, yet they accounted for less than 10% of all mushroom exposures. All other presumed exposures represented less than 2% of the total number of identified. Because 75% to 95% of mushrooms involved in exposures are never identified, a strategy for making significant decisions with incomplete data is essential.

CLASSIFICATION AND MANAGEMENT

This chapter does not address molds, mildews, and yeasts, which in addition to mushrooms are all categorized as fungi. The unifying principle for fungi is the lack of the photosynthetic capacity to produce nutrition. Survival is achieved by the enzymatic capacity of these organisms to integrate into living materials and digest them. Molds are ubiquitous and often associated with varied adverse health effects such as rhinitis, rashes, headaches, and asthma.²¹ Trichothecenes are mold-related mycotoxins that are discussed in [Chap. 133](#) as potential biological weapons. All other molds are not associated with toxicologic emergencies concerns and are not addressed in this chapter.

Because mushroom species vary widely with regard to the xenobiotics they contain, and because identifying them with certainty is difficult, a clinical system of classification is more useful than a taxonomic system ([Table 120–1](#)). The text and tables that follow utilize the commonest species associated with a particular syndrome or xenobiotic and are not meant to be inclusive of all the exceptionally diverse mushrooms associated with many xenobiotics. In many instances the taxonomy has changed, confusing readers and investigators. For example, the text will use the current nomenclature, whereas the citations will obviously utilize prior nomenclature. In many cases, management and prognosis can be determined with a high degree of confidence from the history and the geographic origin of the mushroom, the initial signs and symptoms, the organ system or systems involved, and coexistent factors or conditions.^{31,58,75,76,104}

TABLE 120–1. Mushroom Toxicity Overview

<i>Representative Genus/Species</i>	<i>Xenobiotic</i>	<i>Time of Onset of Symptoms</i>	<i>Primary Site of Toxicity</i>	<i>Symptoms</i>	<i>Mortality</i>	<i>Specific Therapy*</i>
I <i>Amanita phalloides</i> , <i>A. tenuifolia</i> , <i>A. virosa</i> <i>Galerina autumnalis</i> , <i>G. marginata</i> , <i>G. venenata</i> <i>Lepiota josselynii</i> , <i>L. helveola</i>	Cyclopeptides Amatoxins Phallotoxins	5–24 hours	Liver	Phase I: GI toxicity— N/V/D Phase II: Quiescent Phase III: N/V/D, jaundice, ↑ AST, ↑ ALT	0%–30%	Activated charcoal Hemoperfusion/hemodialysis Penicillin G? N-Acetylcysteine Silibinin
II <i>Gyromitra ambigua</i> , <i>G. esculenta</i> , <i>G. infula</i>	Gyromitrin (metabolite: monomethylhydrazine)	5–10 hours	CNS	Seizures, abdominal pain, N/V, weakness, hepatorenal failure	Rare	Benzodiazepines, Pyridoxine 70 mg/kg IV
III <i>Clitocybe dealbata</i> , <i>Omphalotus olearius</i> , most <i>Inocybe</i> spp	Muscarine	0.5–2 hours	Autonomic nervous system	Muscarinic effects— salivation, bradycardia, lacrimation, urination, defecation, diaphoresis	Rare	Atropine—Adults: 1–2 mg Children: 0.02 mg/kg with a minimum of 0.1 mg
IV <i>Coprinopsis atramentaria</i>	Coprine (metabolite: 1-aminocyclopropanol)	0.5–2 hours	Aldehyde dehydrogenase	Disulfiramlike effect with ethanol, tachycardia, N/V	Rare	Symptomatic care
V <i>Amanita gemmata</i> , <i>A. muscaria</i> , <i>A. pantherina</i>	Ibotenic acid, muscimol	0.5–2 hours	CNS	GABAergic effects, rare delirium, hallucinations, dizziness, ataxia	Rare	Benzodiazepines during excitatory phase

VI <i>Psilocybe cyanescens</i> , <i>P. cubensis</i> <i>Gymnopilus spectabilis</i> <i>Psathyrella loebliae</i>	Psilocybin, psilocin	0.5–1 hours	CNS	Ataxia, N/V, hyperkinesia, hallucinations, illusions	Rare	Benzodiazepines
VII <i>Clitocybe nebularis</i> <i>Chlorophyllum molybdites</i> , <i>C. esculentum</i> <i>Lactarius</i> spp, <i>Paxillus involutus</i>	Various GI irritants	0.3–3 hours	GI	Malaise, N/V/D	Rare	Symptomatic care
VIII <i>Cortinarius orellanus</i> , <i>C. rubellus</i>	Orellanine, orellanine	> 1 day–weeks	Renal	Phase I: N/V Phase II: Oliguria, kidney failure	Rare	Hemodialysis for acute kidney injury
IX <i>Amanita smithiana</i> <i>A. proxima</i>	Allenic norleucine	0.5–12 hours	Renal	Phase I: N/V Phase II: Oliguria, kidney failure	None	Hemodialysis for acute kidney injury

X	<i>Tricholoma equestre</i>	Unidentified	24–72 hours	Muscle (skeletal and cardiac)	Fatigue, nausea, muscle weakness, myalgias, ↑ CK, facial erythema, <i>disseminated intravascular coagulation</i>	25%	Sodium bicarbonate, hemodialysis for acute kidney injury
XI	<i>Clitocybe acromelalgia</i> , <i>C. amoerolens</i>	Acromelic acids	24 hours	Peripheral nervous system	Erythromelalgia paresthesias—hands and feet, dysesthesias, erythema, edema	None	Symptomatic care
XII	<i>Pleurocybella porrigens</i>	Unknown	1–31 days	CNS	Encephalopathy, convulsions, myoclonus in patients with chronic kidney failure	High (30%)	Hemodialysis
	<i>Haploporus rutilans</i>	Polyporic acid	> 12 hours	GI, CNS	N/V, abdominal pain, vertigo, ataxia, drowsiness, encephalopathy	None	Symptomatic care
XIII	<i>Pisillius involutus</i> , ? <i>Clitocybe claviceps</i> , ? <i>Boletus luridus</i>	Immune mediated response to involutin	Following repeated exposure 0.5–3 hours	Red blood cell, kidney	Hemolytic anemia, acute kidney injury	Rare	Hemodialysis
XIV	<i>Lycoperdon perlatum</i> , <i>L. pyriforme</i> , <i>L. gemmatum</i>	Spores	Hours	Pulmonary, GI	Cough, shortness of breath, fever, nausea, vomiting	None	Corticosteroids

*Supportive care (fluids, electrolytes and antiemetics) as indicated.

D = diarrhea; N = nausea; V = vomiting.

Group I: Cyclopeptide Containing Mushrooms

Worldwide most mushroom fatalities are associated with cyclopeptide-containing species.^{5,32,138} In the United States, there are two distinct ranges of the fungus *Amanita* species along the West Coast (California to British Columbia) and along the East Coast (Maryland to Maine).¹³⁶ These cyclopeptide-containing species mushrooms include a number of *Amanita* species, including *A. verna*, *A. virosa*, and *A. phalloides*; *Galerina* spp, including *G. autumnalis*, *G. marginata*, and *G. venenata*; and *Lepiota* species, including *L. helveola*, *L. josserandi*, and *L. brunneoincarnata* (Fig. 120–1).

FIGURE 12-1 Group I: Cyclopeptide containing mushrooms. (A) *Amanita phalloides* and (B) *Amanita virosa*. (Used with permission of John Plischke III.)

Early differentiation of cyclopeptide poisonings from other types of mushroom poisoning is difficult (Fig. 120-2). Patients poisoned with cyclopeptides may be ill enough to seek health care for nausea, vomiting, abdominal pain, and diarrhea, which in the absence of a rigorous detailed history often is attributed to other causes as the patient improves with supportive care. Such patients may be sent home, only to return moribund on a subsequent day. The delayed onset of more serious symptoms is typical of cyclopeptide toxicity and is a critical consideration in assessing the toxicologic potential of any exposure.

FIGURE 120-2 In the more highly specialized and evolved mushrooms, various protective tissues cover the fruit body and its constituent parts during its development. In the mushroom shown, an *Amanita* species, two veils of tissue are involved—one an outer enclosing bag, the universal veil, which ruptures as the fruit body expands to leave a volva at the base and fragments on the cap; the other an inner partial veil covering the developing gills that is pulled away as the cap opens to leave a ring on the stem. (Redrawn, with permission, from Kibby G: *Mushrooms and Toadstools, A Field Guide* : Oxford: Oxford University Press, 1979, p. 14.)

A. phalloides contains 15 to 20 cyclopeptides, each with an approximate weight of 900 Da. The amatoxins (cyclic octapeptides), phallotoxins (cyclic heptapeptides), and virotoxins (cyclic heptapeptides) are the best studied.^{37,71,131} There is no evidence for the toxicity of virotoxins in humans. Of these three chemically similar cyclopeptide molecules, phalloidin (the principal phallotoxin) appears to be a rapid-acting toxin, whereas amanitin tends to cause more delayed manifestations.¹⁰⁸ Phalloidin crosses the sinusoidal plasma membranes of hepatocytes by a carrier-mediated process. This process is shared by bile salts and can be prevented in the presence of extracellular bile salts, suggesting competitive inhibition. A sodium-independent bile salt transporting system may be responsible for phalloidin hepatic uptake, elimination, and detoxification.⁸⁵ Phalloidin interrupts actin polymerization and impairs cell membrane function, but because of its limited oral absorption it appears to have minimal toxicity, restricted mostly to GI dysfunction.

The amatoxins are the most toxic of the cyclopeptides, leading to hepatic, renal, and central nervous system (CNS) damage. These polypeptides are heat stable.³⁴ α -Amanitin is the principal amatoxin responsible for human toxicity following ingestion. Approximately 1.5 to 2.5 mg amanitin can be obtained from 1 g of dry *A. phalloides*, and as much as 3.5 mg/g can be obtained from some *Lepiota* spp.^{92,96,131} A 20-g mushroom contains well in excess of the 0.1 mg/kg amanitin considered lethal for humans.³³ α -Amanitin and β -amanitin have comparable toxicity in animal models.³⁶

The amanitins are poorly but rapidly absorbed from the GI tract.⁶³ Amatoxins show limited protein binding and are present in the plasma at low concentrations for 24 to 48 hours.⁶³ α -Amanitin hepatocellular entry appears to be facilitated by a sodium-dependent bile acid transporter. Several studies demonstrate that the sodium taurocholate cotransporter polypeptide, a member of the organic anion-transporter polypeptide OAT polypeptide family localized in the sinusoidal membranes of human hepatocytes, facilitates hepatocellular α -amanitin uptake.^{57,78} Once inside the cells the cytotoxicity amanitin results from its interference with RNA polymerase II, preventing the transcription of DNA.^{81,114} α -Amanitin may be enterohepatically recirculated. Target organs are those with the highest rate of cell turnover, including the GI tract epithelium, hepatocytes, and kidneys. Amatoxins do not appear to cross the placenta, as demonstrated by the absence of fetal toxicity in severely poisoned pregnant women.^{7,14,118}

In an intravenous radiolabeled amatoxin study in dogs, 85% of the amatoxin was recovered in the urine within the first 6 hours, whereas less than 1% was found in the blood at that time.³⁸ Amatoxins can be detected by high-performance liquid chromatography,⁶³ thin-layer chromatography, ion trap mass spectrometry,⁴² and radioimmunoassay in gastroduodenal fluid, serum, urine, stool, and liver and kidney biopsies for several days following an ingestion.^{36,37,70}

Some of the toxicokinetic analyses following unquantified ingestions demonstrate 12 to 23 μ g amatoxin excretion in the urine over 24 to 66 hours, of which 60% to 80% occurred during the first 2 hours of collection. The extreme variabilities of the type and quantity of ingested, the host, and the management make interpretations exceedingly difficult.¹²⁵ In another series, total maximal urinary α - and β -amanitin excreted over 6 to 72 hours were 3.19 and 5.21 mg, respectively. Two-thirds of the patients had total amanitin excretion greater than 1.5 mg.⁶³ Urinary amanitin excretion concentrations differ by several orders of magnitude. Whether the variation results from exposure dose, time following ingestion, or laboratory technique is unclear. Several techniques for quantitative and qualitative evaluation of urinary amanitin are under investigation.^{17,18,96,118}

Clinical. Phase I of cyclopeptide poisoning resembles severe gastroenteritis, with profuse watery diarrhea not occurring until 5 to 24 hours after ingestion. Some consider the early onset (less than 8 hours) of diarrhea as a predictive factor for hepatic failure and the need for liver transplantation.³⁴ whereas this is not supported by most other case series reviewed. It is typically considered that the onset of symptoms before 5 hours is strong support for another non-Amanita species cause for the gastrointestinal distress. Supportive fluid and electrolyte replacement leads to transient improvement during phase II, which occurs between 12 and 36 hours after ingestion.^{96,138} However, despite such supportive care, phase III, manifested by hepatic and renal toxicity and death, may ensue 2 to 6 days after ingestion.⁵ Pancreatic toxicity may rarely occur.⁴⁸ The initial hepatotoxicity begins within the second phase, but clinical hepatotoxicity (Chap. 23) with elevated concentrations of bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT), hypoglycemia, jaundice, and hepatic coma are not manifest until 2 to 3 days after ingestion. Pathologic manifestations include steatosis, central zonal necrosis, and centrilobular hemorrhage, with viable hepatocytes remaining at the rims of the larger triads. Lobular architecture remains intact (Fig. 23-3).⁵

Cyclopeptide toxicity alters the hormones that regulate glucose, calcium, and thyroid homeostasis, resulting in widespread endocrine abnormalities.⁶⁸ Insulin and C-peptide concentrations are elevated at a stage of poisoning prior to hepatic and renal compromise.^{29,68} These findings are suggestive of direct toxicity to pancreatic β cells, resulting in release of preformed hormone or induction of hormone synthesis. This insulin release necessitates vigilance for hypoglycemia prior to hepatocellular damage. Serum calcitonin concentrations may be elevated, and hypocalcemia may be present. Thyroxine concentrations may be depressed and triiodothyronine concentrations undetectable, whereas thyroid-stimulating hormone concentrations may not be elevated. These thyroid-related findings were reported in a single study and merit further investigation.⁶⁸

In a series of 10 patients exposed to diverse *Lepiota* spp, 50% developed a mixed sensory and motor polyneuropathy. Most of the patients spontaneously recovered within one year, although a single patient developed progressive clinical and electromyographic deterioration.⁹⁸ These neuropathic findings have not been recognized in other case reports.

Treatment. The search for treatments has been vigorously pursued in Europe because of the persistently large number of amatoxin victims each year.⁴⁷ Survival rates in case series of variable numbers of patients poisoned by *A. phalloides* who received supportive care, fluid and electrolyte repletion, high-dose penicillin G, dexamethasone, or thioctic acid are between 70% and 100%.^{47,56,62,88,90,100,138} Many of these case series have excellent survival rates with extremely variable therapeutic interventions, limiting the capacity to determine the need for or efficacy of most of the standard conservative therapeutic regimens.

Fluid and electrolyte repletion and treatment of hepatic compromise are essential. Intravenous 0.9% sodium chloride solution and electrolytes usually are necessary because of substantial fluid loss due to vomiting and diarrhea. Dextrose repletion may be necessary because of nutritional compromise, hepatic failure, or glycogen depletion. Activated charcoal both adsorbs the amanitins and improves survival in laboratory animals.³⁶ Emesis, lavage, and catharsis are not necessary unless the patient presents within several hours after the ingestion because any substantial quantity of ingested toxin almost invariably induces emesis and catharsis. In an analysis¹¹ of the AAPCC Toxic Exposure Surveillance System (TESS) database of unintentional mushroom exposures in children from 1992 to 2005 it is suggested that a syrup of ipecac treated subgroup compared to an activated charcoal or no intervention group showed the smallest percentage of moderate or major outcomes. Activated charcoal is safe, logical, and a valuable therapeutic strategy. Although the clinical presentation often is delayed, 1 g/kg body weight of activated charcoal should be given orally every 2 to 4 hours (if the patient is not vomiting) or by continuous nasogastric infusion. Continuous nasogastric duodenal aspiration is used by multiple groups (mainly European) to remove amatoxins secreted in the bile; others use an even more difficult biliary drainage approach to disrupt the enterohepatic recirculation of the amatoxin.⁸⁴ Although there is theoretical support for early quantitative toxin removal due to substantial biliary concentration, the total quantity and actual gastroduodenal concentration remains low, offering inadequate clinical data to support gastroduodenal or biliary drainage.⁶⁴

Thioctic (α -lipoic) acid initially was reported to be beneficial in treating the amatoxin-induced liver toxicity in several different animal models, and a number of uncontrolled clinical trials in humans followed.⁵ Because of its potential effects as a coenzyme in the tricarboxylic acid cycle or as a free radical scavenger, thioctic acid was credited for the survival of 39 of 40 patients reportedly, but not definitively, poisoned by *A. phalloides*.⁷³ Hypoglycemia is a common feature of thioctic acid therapy for *Amanita* poisoning, but whether hypoglycemia results from direct toxicity of the drug or is secondary to hepatic damage is unclear. Despite the initial success, thioctic acid was not effective in various other studies and is no longer recommended.^{45,46}

Several laboratory investigations in mice and rats suggest that 1 g/kg penicillin G (1 g = 1,600,000 Units) may have a time- and dose-dependent protective effect.^{49,50} These results are limited because the amatoxins were administered intraperitoneally, resulting in the death of untreated animals 12 to 24 hours later. Additional investigations demonstrated that 1 g/kg penicillin G administered 5 hours after sublethal doses of α -amanitin decreased clinical and laboratory toxicity.⁴⁹ The mechanisms suggested include displacing α -amanitin from albumin, blocking its uptake from hepatocytes, binding circulating amatoxins, and preventing α -amanitin binding to RNA polymerase. None of these mechanisms is substantiated,³² and we no longer recommend penicillin G be used unless it is used very shortly after an ingestion as a temporizing gesture.

The active complex of milk thistle (*Silybum marianum*) is silymarin, which is a lipophilic extract composed of three isomeric flavonolignans: silibinin, silychristin, and silydianin. Silibinin represents approximately 50% of the extract, but represents about 70% to 80% of the marketed products.⁶¹ Silibinin, a mixture of Silibinin A and B, competitively inhibits the organic anion transporter (OATP1B3) that is responsible for the uptake and enterohepatic recycling of α -amanitin. Use of silibinin 50 mg/kg in dogs 5 and 24 hours following exposure to α -amanitin suppressed chemical evidence of hepatotoxicity and lethality. These same studies suggest silibinin diminishes α -amanitin enterohepatic circulation. Although silibinin is routinely available as a nonprescription supplement in most pharmacies and appears to be safe and well tolerated in patients with chronic liver disease, no reduction in mortality, improvement in histology at liver biopsy, or biochemical marker has been identified in a systematic review and meta-analysis.⁶¹ A dose of silibinin 20 to 50 mg/kg/d should be used in humans, even though it is not approved as a therapeutic for hepatic disease by the Food and Drug Administration (FDA) in the United States.^{70,129} Currently there is an amatoxin poisoning clinical trial utilizing Legalon SIL (Silibinin) at 20 mg/kg/day IV⁶⁰ (Antidotes in Depth: A36).

Because of its hepatoprotective effects, N-acetylcysteine should be given as an antidote, but no evidence for any specific benefit has been demonstrated. When fulminant hepatic failure is present, N-acetylcysteine should be administered until the patient recovers from the encephalopathy because of its presumptive benefits under these circumstances (Antidotes in Depth: A3).

In animals, cimetidine (a potent CYP2C9/2D6 inhibitor) may have a hepatoprotective effect against α -amanitin,¹⁰⁶ but it

shows no protective effect against phalloidin toxicity.¹⁰⁸ Cimetidine is proposed as a therapeutic intervention,¹⁰⁷ but no available human data support its use, and it is not currently recommended.

A recent randomized murine model of intraperitoneal α -amanitin poisoning comparing treatment with rescue postexposure N-acetylcysteine, benzylpenicillin, cimetidine, thiocetic acid, or silybin was unable to show any laboratory benefit with regard to hepatotoxic manifestations such as aminotransferase concentrations or histologic evidence of hepatonecrosis.¹¹⁹

Forced diuresis, hemodialysis, plasmapheresis,^{64,65} hemofiltration, and hemoperfusion⁴⁰ may be effective shortly after ingestion, but most studies offer neither clinical evidence of benefit nor supportive pharmacokinetic data for any of these therapies.^{70,95,96,110,125,128} Most studies suggest that no circulating amatoxins are present by the time the need for transplantation is evident.³⁰ “Shortly after” is not defined, although these techniques are indicated within 24 hours of a documented ingestion.⁴¹ Plasmapheresis, which is dependent on effective clearance, high plasma protein binding, and a low volume of distribution, does not remove more than 10 μ g of amatoxin. Because of the absence of prospective, controlled studies of exposure to amatoxins, in addition to the extreme variability of success with many regimens, multiple-dose activated charcoal, and supportive care remain the standard therapy. Early recognition of exposure to amanitin is an indication for hemodialysis or hemoperfusion, but most patients likely will no longer have the potential for benefit at the time they develop clinical manifestations of toxicity.⁶⁵ Future therapeutic interventions may be dependent on improved understanding of the hepatocellular bile acid transporter, which is a member of the OAT polypeptide family.^{57,74,78}

Extracorporeal albumin dialysis,³⁹ molecular adsorbent recirculating system (MARS),^{26,84,113,135} and fractionated plasma separation and adsorption system (FPSA; Prometheus system),^{35,124,126} are variant detoxification techniques used in patients with fulminant hepatic failure to remove water-soluble and albumin-bound xenobiotics while providing renal support. The typical delayed time to onset of use of MARS and other extracorporeal liver assist devices in amanitin poisoning invariably limits the potential effects of these systems not to toxin removal but to correction or stabilization of hepatic dysfunction. None of the available studies of these bridging systems are randomized or controlled. The clinical experience is solely in the care of patients with grave hepatotoxicity at a delayed stage limiting any potential for significant conclusions. These two techniques permit time for hepatic regeneration or sufficient bridging time to orthotopic liver transplantation. The criteria and timing for liver transplantation following amatoxin poisoning are far less established than for fulminant viral hepatitis, where grade III or IV hepatic encephalopathy, marked hyperbilirubinemia, and azotemia are the well-established criteria for transplantation (Chap. 23).⁹⁴ Successful transplantations were performed in individuals whose resected livers showed 0% to 30% hepatocyte viability. In these cases, the authors did not wait for progression past grade II encephalopathy or for development of azotemia or marked hyperbilirubinemia.⁹⁴ Criteria for patient selection are essential to avoid unnecessary risk while offering the potential for survival to appropriate candidates who have no functional liver. The grim prognosis associated with hepatic coma secondary to *Amanita* poisoning has led several transplant groups to consider hepatic transplantation for encephalopathic patients with prolonged international normalized ratios (INRs; greater than 6), persistent hypoglycemia, metabolic acidosis, increased concentrations of serum ammonia and AST, and hypofibrinogenemia.^{34,53,54,69,94} There are now case reports of successful liver transplantation for fulminant^{63,67,94} hepatic failure from presumed *A. ocreata*,^{69,137} *A. phalloides*, *A. virosa*,¹⁶ *Lepiota helveola*,⁸⁶ and *L. brunneoincarnata* poisoning.⁹⁸

To enhance the likelihood of success, individuals who manifest symptoms suggestive of hepatotoxic *Amanita*, *Galerina*, or *Lepiota* spp exposure should be told of the potential need for transplantation and, with their consent, be rapidly transferred to a regional liver transplantation center.^{16,34,94}

Group II: Gyromitrin Containing Mushrooms

Members of the gyromitrin group include *Gyromitra esculenta*, *Gyromitra ambigua*, and *Gyromitra infula*. *G. esculenta* enjoys a reputation of being edible in the Western United States but of being toxic in other areas. The most common error occurs in the spring, when an individual seeking the nongilled, brainlike *Morchella esculenta* (morel) finds the similar *G. esculenta* (false morel) (Fig. 120–3).

FIGURE 120–3 Group II: Gyromitrin containing mushrooms. A true morel (*Morchella* spp) on the left is compared to a false morel (*Gyromitra esculenta*) on the right. (Used with permission of John Trestrail.)

These mushrooms are found commonly in the spring under conifers and are easily recognized by their brainlike appearance. Poisonings with these mushrooms are exceptionally uncommon in the United States, representing less than 1% of all recognized events, whereas these poisonings are considered more common in Europe. Certain cooking methods may destroy the toxin, but because of the potential for toxicity, all members of this mushroom family should be avoided.

Gyromitra mushrooms contain the nonvolatile insoluble gyromitrin which on hydrolysis yields a family of N-methyl-N-formyl hydrazones, which on subsequent hydrolysis split into aldehydes and N-methyl-N-formyl hydrazine.³ Subsequent hydrolysis of N-methyl-N-formyl hydrazine yields monomethylhydrazine (Fig. 120–4). The hydrazine moiety reacts with pyridoxine, resulting in inhibition of pyridoxal phosphate-related enzymatic reactions (Figs. 58–2 and 58–3). This interference with pyridoxal phosphate disrupts the function of the inhibitory neurotransmitter γ -aminobutyric acid (GABA).⁷⁵ This decrease in GABA is thought to contribute to the diverse neurological manifestations typically associated with this ingestion.

FIGURE 120–4 Gyromitra mushrooms contain gyromitrin which undergoes hydrolysis to yield a family of N-methyl-formyl hydrazines. These molecules on subsequent hydrolysis yield N-methyl-N-formyl hydrazine and monomethylhydrazine.

acetylcholine. Because muscarine lacks an ester bond, it is not hydrolysed by acetylcholinesterase.

Significant toxicity is uncommon, limiting the need for more than supportive care. Rarely, atropine (1–2 mg given IV slowly for adults or 0.02 mg/kg with a minimum of 0.1 mg IV for children) can be titrated and repeated as frequently as indicated to reverse symptomatology.

No current, clinically available, analytic techniques can identify muscarine, although high-performance liquid chromatography would be appropriate for investigative purposes.

Group IV: Coprine Containing Mushrooms

Coprine

Coprinus mushrooms, particularly *C. atramentarius*, (*Coprinopsis atramentaria*) contain the xenobiotic coprine (Fig. 120–6A). These mushrooms grow abundantly in temperate climates in grassy or woodland fields. They are known as “inky caps” because the gills that contain a peptidase autodigest into an inky liquid shortly after picking. The edible member of this group, *Coprinus comatus* (shaggy mane) (Figs. 120–6B and 6C) is nontoxic, and probably its misidentification results in collectors’ errors. Coprine, an amino acid, its primary metabolite, 1-aminocyclopropanol,^{20,83,120} or, more likely, a secondary in vivo hydrolytic metabolite, cyclopropanone hydrate, has a disulfiramlike effect (Fig. 120–7, see Chap. 79).¹³⁴ Although both of these metabolites appear to inhibit aldehyde dehydrogenase, the most stable in vivo inhibitory effect is manifested by cyclopropane hydrate.¹³⁴ Inhibition of acetaldehyde dehydrogenase results in accumulation of acetaldehyde and its accompanying adverse effects, which takes at least 0.5 to 2 hours if the patient ingests alcohol and a coprine containing mushroom concomitantly. For the subsequent 48 to 72 hours following coprine-containing mushroom ingestion if ethanol ingestion occurs toxicity may ensue. Within 0.5 to 2 hours of ethanol ingestion, an acute disulfiram effect is noted, with tachycardia, flushing, nausea, and vomiting. The simultaneous ingestion of the mushroom and alcohol does not result in immediate clinical manifestations because inhibition of aldehyde dehydrogenase occurs following coprine metabolism and the in vivo production of cyclopropane hydrate. Treatment is symptomatic with fluid repletion and antiemetics such as metoclopramide or ondansetron, although clinical manifestations usually are mild and resolve within several hours. Prophylactic use of fomepizole immediately following ingestion of ethanol and coprine-containing mushrooms has a theoretical basis, but no case reports or studies are published. This group of mushrooms rarely causes fatalities.

FIGURE 120–6 Group IV: Coprine containing mushrooms. (A) *Coprinopsis atramentaria*; (B) and (C) show *Coprinus comatus* (shaggy mane). Image (B) shows an early form which later is self digested demonstrating the gill liquefaction in image (C). (Image A Used with permission of John Plischke III, and images B and C used with permission of Lewis Nelson.)

FIGURE 120–7 The *Coprinus* mushrooms contain coprine, an amino acid which is rapidly hydrolysed to 1-

aminocyclopropanol and subsequently cyclopropane hydrate. It is this last metabolite which most likely has the disulfiramlike effect.

Group V: Ibotenic Acid and Muscimol Containing Mushrooms

Most of the mushrooms in this class are primarily in the *Amanita* species, which includes *A. muscaria* (fly agaric), *A. pantherina*, and *A. gemmata* (Fig. 120–8). They exist singly and are scattered throughout the US woodlands. The brilliant red or tan cap (pileus) is that of the mushroom commonly depicted in children's books and is easily recognized in the fields during summer and fall.

FIGURE 120–8 Group V: Muscimol containing mushrooms. This image of *Amanita muscaria* highlights different developmental forms and colors. (Used with permission of John Plischke III.)

Small variable quantities of the isoxazole derivatives ibotenic acid and muscimol are found in these mushrooms, which have been used in religious customs throughout history. Ibotenic acid is structurally similar to the stimulatory neurotransmitter glutamic acid. The stereochemistry of muscimol is very similar to that of the neurotransmitter GABA and may act as a GABA agonist.

Most patients who develop symptoms intentionally ingested large quantities of these mushrooms while seeking a hallucinatory experience. Within 0.5 to 2 hours of ingestion, these mushrooms produce the GABAergic manifestations of somnolence, dizziness, hallucinations, dysphoria, and delirium in adults, and the excitatory glutamatergic manifestations of myoclonic movements, seizures, and other neurologic findings predominate in children.⁸

Treatment is invariably supportive. Most symptoms respond solely to supportive care, although a benzodiazepine is appropriate for excitatory CNS manifestations.

Group VI: Psilocybin Containing Mushrooms

Psilocybin-containing mushrooms include *Psilocybe cyanescens*, *Psilocybe cubensis*, *Conocybe cyanopus*, *Panaeolus cyanescens*, *Gymnopilus spectabilis*, and *Psathyrella foenicis* (Fig. 120–9). These mushrooms have been used for native North and South American religious experiences for thousands of years. They grow abundantly in warm, moist areas of the United States. Drug culture magazines and Internet sources advertise mail-order kits containing *P. cubensis* spores to grow “magic mushrooms” domestically.

FIGURE 120–9 Group VI: Psilocybin containing mushrooms. Three examples of hallucinogenic mushrooms: (A) *Psilocybe cyanescens*, (B) *Psilocybe caerulipes*, and (C) *Gymnopilus spectabilis*. (Used with permission of John Plischke III.)

Toxicity from this group is common because of the popularity of hallucinogens.¹² Psilocybin is rapidly and completely hydrolyzed to psilocin in vivo. Serotonin, psilocin, and psilocybin are very similar structurally and presumably act at a similar 5-HT₂ receptor site. The effects of psilocybin as a serotonin agonist and antagonist are discussed in Chaps. 14 and 82.

The psilocybin and psilocin indoles, like those of lysergic acid diethylamide (LSD), rapidly (within one hour of ingestion) produce CNS effects, including ataxia, hyperkinesia, visual illusions, and hallucinations. Some patients manifest gastrointestinal distress, tachycardia, mydriasis, anxiety, lightheadedness, tremor, and agitation. Most manifestations are recognized within 4 hours of ingestion with a return to normalcy within 6 to 12 hours.⁵⁹ Rare cases of renal failure,^{51,97} seizures, and cardiopulmonary arrest¹² are associated with psilocybin-containing species. However, such associations should always be questioned when reported in a substance-using individual potentially simultaneously exposed to other xenobiotics.

A single patient who intravenously administered an extract of *Psilocybe* mushrooms experienced chills, weakness, dyspnea, headache, severe myalgias, vomiting associated with hyperthermia, hypoxemia, and mild methemoglobinemia.²⁷

Treatment for hallucinations usually is supportive, although a benzodiazepine may be necessary when reassurance proves inadequate.

Group VII: Gastrointestinal Toxin Containing Mushrooms

By far the largest group of mushrooms is a diverse group that contains a variety of ill-defined GI toxins. Many of the hundreds of mushrooms in this group fall into the “little brown mushroom” category. Some *Boletus* spp, *Lactarius* spp, *O.*

olearius, Rhodophyllus spp, Tricholoma spp, Chlorophyllum molybdites, and Chlorophyllum esculentum are mistaken for edible or hallucinogenic species. A frequently reported error^{4,52,123} is the confusion of the jack-o'-lantern (Omphalotus illudens) with the edible species of chanterelle (Cantharellus cibarius).

The toxins associated with this group are not identified. The malabsorption of proteins and sugars, such as trehalose, and the ingestion of a mushroom infected or partially digested by microorganisms or allergy may be responsible for symptoms. GI toxicity occurs 0.3 to 4 hours after ingestion when epigastric distress, malaise, nausea, vomiting, and diarrhea are evident. Treatment includes fluid resuscitation with control of vomiting and diarrhea. The clinical course is brief and the prognosis excellent. Those mushroom ingestions resulting in gastrointestinal toxicity more than 4 hours after ingestion are considered in Table 120–2. When symptoms seem to persist, the clinician must consider a mixed ingestion of another potentially toxic mushroom group.

TABLE 120–2. Mushroom Toxicity: Correlation between Organ System Affected, Time of Onset of Symptoms, and Mushroom Constituent Responsible

Organ System	Time of Onset		
	Early: <5 hours	Middle: 5–24 hours	Late: >24 hours
Gastrointestinal	Allenic norleucine Cepine Gastrointestinal toxins Muscarine	Allenic norleucine Amatoxin Gyromitrin	Orellanine and orellanine
Hepatic			Amatoxin
Immunologic	Involutin Spores		
Neurologic	Ibotenic acid and muscimol Psilocybin	Gyromitrin	Acromelic acid Gyromitrin Polyporic acid
Renal			Allenic norleucine Orellanine and orellanine

Rarely, clinical presentations are life threatening, with hypovolemic shock necessitating fluids and vasopressors.¹¹⁵ Resolution of symptoms usually occurs within 6 to 24 hours. The clinical courses associated with specific mushroom ingestions are variable.⁸ Death is rare.

Group VIII: Orellanine and Orellanine Containing Mushrooms

Cortinarius mushrooms, such as C. rubellus (Fig. 120–10) and C. orellanus, are commonly found throughout North American and Europe.^{19,66,109} The C. orellanus toxin orellanine is reduced by photochemical degradation to orellanine a bipyridyl molecule that is further reduced to the nontoxic orelline.^{2,91,101} The toxic compound orellanine is a hydroxylated bipyridine compound activated by its metabolism through the cytochrome P450 system. Toxicologically, these molecules are similar to paraquat and diquat and may have comparable mechanisms of action, although precise knowledge is limited (Chap. 112). Other nephrotoxins, such as cortinarines, are isolated from certain Cortinarius spp¹⁰⁷ and result in tubular damage, interstitial nephritis, and tubulointerstitial fibrosis.

FIGURE 120–10 Group VIII Orellanine and Orellinine containing mushrooms: *Cortinarius rubellus*. (Used with permission of Astrid Holmgren, Swedish Poisons Information Centre.)

Orellanine is rapidly removed from the plasma within 48 to 72 hours and concentrated in the urine in a soluble form. It can be detected in the plasma at the time of clinical symptoms by some investigators⁹⁹ but not by other investigators.¹⁰² Thin-layer chromatography on renal biopsy material can detect orellanine long after clinical exposure.^{99,102}

Initial symptoms occur 24 to 36 hours after ingestion and include headache, chills, polydipsia, anorexia, nausea, vomiting, and flank and abdominal pain. The largest case review demonstrated that numerous patients repetitively ingested the *Cortinarius* spp prior to diagnosis.²⁸ Oliguric renal failure may develop several days to weeks after initial symptoms.¹³ The only initial laboratory abnormalities may be hematuria, leukocyturia, and proteinuria. Nephrotoxicity is characterized by interstitial nephritis with tubular damage and early fibrosis of injured tubules with relative glomerular sparing.^{19,109} Hepatotoxicity is rarely reported.¹³ Hemoperfusion, hemodialysis, and renal transplantation are used for the treatment of renal failure.^{13,28} No evidence suggests that secondary detoxification by plasmapheresis or hemoperfusion is of any benefit in preventing chronic renal failure even when initiated in the first 48 hours.^{28,70,99} The data are inadequate to define management or prognosis precisely, as many patients improve rapidly, while some require temporary intermittent hemodialysis and others require chronic therapy for persistent renal failure.¹³ No laboratory or clinical parameters predicting the individual reactions to the toxins are available. Although case reports in the literature commonly lack definitive proof of ingestion or confirmation of toxin presence, the more rapid the onset of GI and renal manifestations, the greater the risk of both acute and chronic renal failure.²⁸

Group IX: Allenic Norleucine Containing Mushrooms

Amanita smithiana poisoning is reported in the Pacific Northwest (Fig. 120–11).^{77,122,127,130} Because the mature specimen often lacks any evidence of a partial or universal veil, these mushrooms are not recognized as *Amanita* species. It appears that all of the poisoned individuals were seeking the edible pine mushroom matsutake (*Tricholoma magnivelare*), a highly desirable look-alike. The *A. smithiana*, *A. proxima*, *A. abrupta* and *A. pseudoporphyria*, and *A. abrupta* possess two amino acid toxins: allenic norleucine (amino-hexadienoic acid) and possibly 1,2-amino-4-pentynoic acid.^{23,93,139} A similar case report following the ingestion of *A. proxima* in Southern France resulted in gastrointestinal and renal manifestations.²⁵ In vitro renal epithelial tissue cultured with allenic norleucine developed necrotic morphologic changes similar to those that occur following *A. smithiana* ingestion.⁹³ In mice the extract of *A. abrupta* is hepatotoxic, which suggests that hepatotoxins and nephrotoxins are present in this species.¹³⁹

FIGURE 120-11 Group IX Allenic norleucine containing mushrooms: (A) *Amanita smithiana* compared to (B) *Tricholoma magnivelare* (matsutake, the mushroom with which it has been mistaken). (Used with permission of John Plischke III.)

Initial symptoms were noted from 0.5 to 12 hours following ingestion of either raw or cooked specimens. GI manifestations, including anorexia, nausea, vomiting, abdominal pain, and diarrhea, occurred frequently, accompanied by malaise, sweating, and dizziness. In some cases, vomiting and diarrhea persist for several days. The patients typically presented for care 3 to 6 days after ingestion, at which time they were oliguric or anuric. Acute kidney injury manifested 4 to 6 days following ingestion with marked elevation of BUN and creatinine. Lactate dehydrogenase and ALT concentrations frequently were elevated, whereas amylase, AST, alkaline phosphatase, and bilirubin were only infrequently abnormal.

Risk of toxicity was greatest in older patients and in patients with underlying renal insufficiency. Patients who required hemodialysis underwent the procedure two to three times per week for approximately one month until recovery. None of the patients in the three series died.

There is no known antidote for these nephrotoxins. Activated charcoal, although of no proven benefit, should be used in standard doses when a patient in the Northwest United States presents with early GI manifestations after mushroom ingestions. The clinician will be forced to consider the circumstances of ingestion to assess the probability of *A. smithiana* ingestion as opposed to ingestion of mushrooms containing a GI toxin.

In view of the substantial morbidity associated with *A. smithiana* ingestions, historic, clinical, and/or temporal evidence of this ingestion should lead to charcoal hemoperfusion or hemodialysis as a strong consideration when the patient presents in the early phase of exposure. When a patient presents with renal compromise several days, as opposed to weeks, following mushroom ingestion and with a history of early, as opposed to delayed, GI manifestations, the clinician may be able to suggest *A. smithiana* as the etiology compared to *Cortinarius* spp exposure.

Group X: Rhabdomyolysis Associated Mushrooms

There are several reports of *Tricholoma equestre* (*Tricholoma flavovirens*) ingestions in Poland and France, where although this mushroom is considered “edible choice,” it has resulted in significant myotoxicity.^{24,89} In the first report 12 patients who ingested *T. equestre* mushrooms for 3 consecutive days developed severe rhabdomyolysis that was lethal in three cases.⁶ All patients developed fatigue, muscle weakness, and myalgias 24 to 72 hours following the last mushroom meal. The individuals also developed facial erythema, nausea without vomiting, and profuse sweating. The mean maximal creatine phosphokinase (CK) was 226,067 U/L in women and 34,786 U/L in men, with some values greater than 500,000 U/L. Electromyography revealed muscle injury with evidence of myotoxic activity. The biopsies showed myofibrillar injury and edema consistent with an acute myopathy.

Dyspnea, muscle weakness, acute myocarditis, dysrhythmias, congestive heart failure, and death ensued in three patients. Autopsy demonstrated myocardial lesions identical to those found in the peripheral muscles. Although muscle toxicity was reproduced using *T. equestre* extracts in a mouse model, the etiology of the toxicity is not defined.⁶ All the triterpenoids, sterols, indoles, and acetylenic compounds extracted from these mushrooms previously were assumed to be without toxicity. Currently all the clinical experience originates from Europe where these mushrooms are considered choice and eaten extensively; no cases are reported in the United States.

Group XI: Erythromelalgia Acromelic Acid Containing Mushrooms

Acromelic acids D and E

D: $R_1 = \text{COOH}$; $R_2 = \text{H}$

E: $R_1 = \text{H}$; $R_2 = \text{COOH}$

A poorly defined syndrome originally recognized in Japan,⁸⁷ recently in France⁹ following the ingestion of various *Clitocybe* species (*C. acromelalga* and *C. amoenolens*), and not recognized currently in the United States. The toxic substances acromelic acids A–E have been isolated. These molecules are similar to kainic acid and are of the pyrrolidine dicarboxylic acid family, which act as ionotropic glutamate receptors. The syndrome typically occurs more than 24 hours following ingestion. Patients typically develop paraesthesias of distal extremities followed by paroxysms of severe burning dysesthesias lasting several hours. The extremities show edema and erythema. These manifestations respond variably to symptomatic and supportive care and resolve completely within several months.

Group XII: Polyporic Acid and Other Mushroom Constituents Resulting in Encephalopathy

Two groupings of toxic mushroom ingestion syndromes result in encephalopathy. In the first group, *Pleurocybella porrigens* is commonly eaten in Japanese miso soup without any adverse effects. However, their ingestion by patients with chronic renal failure resulted in delayed manifestations of encephalopathy.⁵⁵ Three-quarters (24 of 32) of the affected patients were undergoing hemodialysis at the time of the presumed poisoning. The delay from time of ingestion to the development of an altered consciousness, convulsions, myoclonus, dysarthria, dysesthesias, ataxia, respiratory failure, or death was between 1 and 31 days. No prior toxic link or known toxin in these commonly ingested mushrooms is recognized.

The second group of mushrooms associated with encephalopathy is the *Hapalopilus rutilans* reported in a German case series. More than 12 hours after ingestion an adult and two children developed nausea, vomiting, and abdominal pain; aminotransferase and creatine concentration elevations; and CNS abnormalities. Vertigo, ataxia, visual disturbances, and somnolence were reported.^{72,104} In each case the urine was a violet color, the color being noted when polyporic acid is placed in an alkaline solution. Polyporic acid, a dehydroquinone derivative (2,5-dihydroxy-3,6-diphenyl-1,4 benzoquinone), a constituent of these mushrooms, is a dehydroorotate dehydrogenase (an enzyme in the biosynthesis of pyrimidine) inhibitor that resulted in comparable clinical and biochemical manifestation when administered to rats.⁷² Symptomatic treatment is indicated with more specific therapy should hepatic or renal compromise be significant.

Group XIII: Immune Mediated Hemolytic Anemia

A small number of patients with ingestions of *Paxillus involutus*, and possibly *Clitocybe claviceps* and *Boletus luridus*, develop early onset mild GI symptoms followed by an immune-mediated hemolytic anemia, hemoglobinuria, oliguria, and renal failure. IgG antibodies to a *Paxillus* extract-containing involutin⁷⁰ were detected by a hemagglutination test in these patients.^{132,133} This syndrome occurs in Europe, typically among those who have eaten *P. involutus* numerous times in the past.

Group XIV: Lycoperdonosis

Puffball mushrooms (*Lycoperdon perlatum*, *Lycoperdon pyriforme*, or *Lycoperdon gemmatum*) are edible in the fall and can (upon decay or drying) release large numbers of spores following compression, fracture, or shaking (Fig. 120–12). Lycoperdonosis is directly related to massive exposure to spores, although many consider the syndrome an allergic bronchoalveolitis. This syndrome occurs in patients following acute inhalation of spores as an alternative or

complementary therapy for epistaxis¹¹⁷ and in adolescents for various experimental reasons.²² Massive inhalation, insufflation, and chewing of spores can lead to the development of nasopharyngitis, nausea, vomiting, and pneumonitis within hours. Over a period of several days, cough, shortness of breath, myalgias, fatigue, and fever develop. Rarely, patients require intubation because of pulmonary compromise associated with diffuse reticulonodular infiltrates.²² Lung biopsy demonstrates an inflammatory process with the presence of *Lycoperdon* spores.¹¹⁷ Patients treated with corticosteroids such as prednisone and antifungals such as amphotericin B recovered within several weeks without sequelae.

FIGURE 120–12 Puff balls: (A) *Lycoperdon pyriforme* and (B) *Lycoperdon perlatum*. (Used with permission of John Plischke III.)

MANAGEMENT

Because ingestion of certain mushrooms may lead to toxicity with substantial morbidity or mortality, patients with suspected mushroom ingestions require rigorous management. A serious effort at precise identification of the genus and species involved will make assessment, management, and follow-up easier and more logical. Beuhler and coworkers utilizing the AAPCC Toxic Exposure Surveillance System suggest that the treatment of exposures to mushrooms in children with syrup of ipecac decreases morbidity. Although this analysis suggestive of benefit in unknown exposures may be unrelated to ingestions of toxic mushrooms, the use of the syrup of ipecac is logical.¹¹ The basic regimen of adsorption should include activated charcoal if potentially toxic mushrooms are ingested or substantial enterohepatic recirculation is suspected. If nausea and vomiting persist, an antiemetic can be used to ensure that the patient can retain activated charcoal. Appropriate life support measures should be instituted as necessary. Fluids, electrolytes, and dextrose repletion, as needed, are essential.

There is a wide variability in quantity and type of xenobiotic present in mushrooms according to geography, local conditions, and individual susceptibility. The clinical course for *A. smithiana* poisoning has led us to suggest an alteration in the initial approach to patients in the northwest United States who have early onset (0.5–5 hours) of GI distress following mushroom ingestion as *A. smithiana* has a significant risk of renal failure. Prior to the recognition of this mushroom poisoning, all patients who had early onset of nausea, vomiting, diarrhea, and abdominal cramps were presumed to be poisoned by a member of the groups containing either the GI toxins or muscarine. The routine use of specific antidotes should be avoided because they usually are unnecessary.

DISPOSITION

It is important to remember that many patients with mushroom ingestions present with signs and symptoms suggestive of mixed poisonings. Whereas some ingestions produce “purer” symptom complexes than others, some ingestions, such as those of *A. muscaria*, produce GI and CNS effects, and still other ingestions, such as those of *Cortinarius* spp, have acute GI and delayed renal manifestations. Treatment or partial treatment may further confound the assessment. In addition, it is essential to remember that any acute GI disorder actually may be the manifestation of mushroom toxicity. In the spring and fall, in areas with moderate weather and humidity, it is particularly important to consider intentional or unrecognized exposure to mushroom toxins, although a logical approach to management is impossible in the absence of a precise history.

Because the clinical course of mushroom poisoning can be deceptive, all patients who manifest early gastrointestinal symptoms (less than 5 hours) and remain symptomatic for several hours despite supportive care ([Tables 120–1 and 120–2](#)) should be admitted to the hospital. In this group of patients inhabiting the Pacific Northwest, *A. smithiana* should be of particular concern. Although acute kidney injuries will likely not occur for several days necessitating careful follow-up. Patients whose delayed initial presentation (greater than or equal to 5 hours) is suggestive of amatoxin exposure should be hospitalized, as should any patient postingestion who cannot be followed safely or reliably as an outpatient. [Tables 120–1 and 120–2](#) list the characteristic times of appearance and evolution of symptoms caused by mushroom xenobiotics. Confusion may result from atypical clinical manifestations or, commonly, ingestion of several different mushrooms species, some of which may produce early symptoms and others delayed toxicity. Patients with certain types of ingestions may appear to improve initially with only supportive care. This latency period, which is characteristic of *Amanita* spp, may not be appreciated when several different species are eaten simultaneously. However, because hepatotoxicity leading to death may not appear until 2 to 3 days after ingestion (amatoxins) and nephrotoxicity may not appear for 3 to 21 days (orellanine and allenic norleucine), all patients with symptoms as do children with unknown ingestions require subsequent follow-up.

IDENTIFICATION

General

Visualizing and analyzing the gross, microscopic, or chemical characteristics of the ingested mushroom remain vital strategies that are infrequently used. When the whole mushroom or parts are unavailable, the diagnosis must be based on the clinical presentation. No rapidly available studies in EDs or clinical chemistry laboratories are available to assist with management. The development of a rapid clinical test for amatoxins,^{17,18,70} gyromitrin, orellanine, and allenic norleucine would be useful and permit early use of hemodialysis or hemoperfusion and greater vigilance with regard to use of hemodialysis. We have not yet achieved the ability to use thin-layer chromatography, high-performance liquid chromatography, gas chromatography, or gas chromatography-mass spectrometry in a clinically relevant manner. In Italy and Japan real time, polymerase chain reaction (PCR) has been developed for multiple species for experimental evaluations of cooked mushrooms and gastric aspirates. Future development of this technique might prove clinically useful.^{33,82}

Although mushroom identification is a difficult task, this section may be helpful to the clinician dealing with a suspected case of mushroom toxicity. However, it is generally best to rely on symptomatology, not mushroom appearances, to confirm a diagnosis. As a general rule, positive identification of the mushroom should be left to the mycologist or toxicologist.⁴³

The most important anatomic features of both edible and poisonous mushrooms are their pileus, stipe, lamellae or gills, and volva.

- Pileus: Broad, caplike structure from which hang the gills (lamellae), tubes, or teeth.
- Stipe: Long stalk or stem that supports the cap; the stipe is not present in some species.
- Lamellae: Platelike or gilllike structures on the undersurface of the pileus that radiate out like the spokes of a wheel. The spores are found on the lamellae. Some mushrooms have pores or toothlike structures on their pili, which contain the spores. The mode of attachment of the lamellae to the stipe is noteworthy in making an identification.
- Volva: Partial remnant of the veil found around the base of the stipe in some species.
- Veil: Membrane that may completely or partially cover the lamellae, depending on the stage of development. The “universal” veil covers the underside, the spore-bearing surface of the pileus.
- Annulus: Ringlike structure that may surround the stipe at some point below the junction, with the cap that is a remnant of the partial veil.
- Spores: Microscopic reproductive structures that are resistant to extremes in temperature and dryness, produced in the millions on the spore-bearing surface (see Lamellae). Of all the characteristics of a particular mushroom species, spores are the least variable, although many mushrooms have similar-appearing spores. A spore print is helpful in establishing an identification. A spore print viewed microscopically is comparable to a bacterial Gram stain. Spore colors range from white to black and include shades of pink, salmon, buff, brown, and purple. Spore color in general is

constant for a species.

The Unknown Mushroom

1. The most important determinant is whether the ingested mushroom is one of the deadly varieties, especially *Amanita*. Outside of the Pacific Northwest, the onset of GI symptoms within 5 hours of ingestion does not result from amatoxin poisoning. In the Pacific Northwest, symptoms may represent *A. smithiana* (allenic norleucine) poisoning ([Tables 120–1 and 120–2](#)).
2. An attempt should be made to obtain either the collected mushrooms or a detailed description of their features. Arrange for transport of the mushroom in a dry paper bag (not plastic). Ensure that the mushroom is neither moistened nor refrigerated, either of which will alter its structure. Remember that gastric contents may contain spores that may be very difficult to find, but can be crucial for analysis.
3. If the mushroom cap is available, make a spore print by placing the pileus spore-bearing surface side down on a piece of paper for at least 4 to 6 hours in a windless area. The spores that collect on the paper can be analyzed for color. White spore prints can be visualized more easily on white paper by tilting the paper and looking at it from an angle.
4. Concomitant with step 3, contact a mycologist and use the best resources available for identification. A botanical garden usually has expert mycologists on staff, or a local mycology club can locate a mycologist. A regional poison center almost always can provide this expertise or locate an expert.
5. If none of the resources in step 4 is accessible, Melzer reagent can be useful in differentiating look-alike species and defining the presence of an amatoxin. A positive reaction is indicated by the development of a dark blue color upon contact with Melzer reagent.⁷⁹ Melzer reagent is a solution of 20 mL water, 1.5 g potassium iodide, 0.5 g iodine, and 20 g chloral hydrate. Staining a sample of the spores with one drop of reagent and then viewing the sample under a microscope helps to determine whether the mushroom is a deadly *Amanita*, with bluish-black “amyloid” reacting round spores. Hospitals are not typically prepared for this type of testing which now often is only of interest to the expert mycologist and rare toxicologist.
6. An additional test used by some is the Meixner reaction. Several drops of 10N to 12N hydrochloric acid are applied to an amatoxin containing mushroom sample squeezed onto newspaper, resulting in a blue reaction.⁷⁰ The reliability of this test is doubtful, and most mycologists prefer to use the Melzer reagent. Although the Meixner test is sensitive, false-negative and false-positive tests are of concern.¹⁰

POISONING PRINCIPLES: MYTHS AND SCIENCE

Differentiating myths from science is a difficult task in any field of medicine. This effort is even more complex when discussing mushrooms. The following principles are of great value in developing a logical approach to a potential ingestion.

1. Wild mushrooms should never be eaten unless an experienced mycologist can absolutely identify the mushroom. Even experts have trouble identifying some mushrooms, yet some foragers boldly indicate that distinguishing edible from toxic mushrooms is “as easy as telling brussels sprouts from broccoli.” Remember the saying, “There are old mushroom hunters, and bold mushroom hunters; but there are no old, bold mushroom hunters.”
2. The toxicology of any species can vary, depending on geographic location. This species confusion is obvious among American immigrants stating unequivocally that “this particular mushroom” was absolutely safe and routinely eaten in the individual’s Asian or European country of origin. A 40-year epidemic in the Yunnan Highlands of China is a classic “mushroom epidemic.” Local investigators¹¹¹ have suggested epidemiologic data implicating *Troga Venenata* for the high incidence of sudden unexplained death (SUD). The work of the Chinese Field Epidemiology Training Program of the Chinese CDC suggests that two amino acids 2R-amino-4S hydroxy-5-hexynoic acid and 2R-amino-5-hexynoic acid found in these mushrooms are lethal xenobiotics in mice, which is a possible explanation for human sudden unexplained death syndrome. Although there is a high degree of suspicion and clinical correlation others have had SUD without ingestions, leading some investigators to believe that the high barium concentrations from victims and family members as well as the presence of barium in the soil, water, and other foods as well as in the previously unspiciated mushrooms (*Troga Venenata*) was causative.¹¹⁶ This discussion is typical of the evolution of understanding of the potential toxicity of a particular mushroom species or the micro-environment.
3. If toxicity is suspected, attempt to obtain samples of the mushrooms eaten, and identify them. Every ED should have a readily available resource on mushrooms, such as one of the major mycology field guides.^{1,15,79,80,103,112} In any case, identification is best made with the aid of the poison center’s consultant mycologist.
4. Mushrooms often are implicated as the cause of an illness when, in fact, infections or other diseases are responsible.

Other etiologies include the mode of preparation (the sauce or wine) or the cooking utensil.

5. There are no absolute generic approaches for evaluating the potential toxicity of a mushroom. Myths suggesting the safety or lack of safety by staining of silver, presence of insects or slugs, peeling off the mushroom cap, or the area of mushroom growth are unreliable or false. Neither odor nor taste is a good predictor of toxicity. Pure white mushrooms, little brown mushrooms, large brown mushrooms, and red-or pink-spored boletus (a mushroom without lamellae) should be considered potentially toxic.
6. Cooking may inactivate some xenobiotics but not others. In general, no wild mushroom should be eaten raw or in large quantities. Examples of toxicity associated with lack of cooking include *Armillariella mellea* (honey mushroom), which usually is well tolerated when cooked but not raw, and *Verpa bohemica* (a morellike mushroom), which is edible but causes illness if eaten in excess. Even the *Morchella esculenta*, the edible choice morel, is well recognized to cause dizziness, tremor, and ataxia when eaten raw in large quantities.¹⁰⁵
7. Associated phenomena may be responsible for or contribute to toxicity. Could insecticides have been sprayed on the mushrooms? Is it an alcohol-related response? Besides the well-known disulfiram reaction involving *C. atramentarius*, other good edibles, including the black morel (*Morchella angusticeps*) and the sulfur polypore (*Laetiporus sulfureus*), can cause adverse reactions if consumed with alcohol. The etiology of these adverse reactions is not understood.
8. “Edible” mushrooms that are allowed to deteriorate become toxic. Therefore, only young, recently matured specimens should be eaten when adequate mycologic support is available.
9. The finding that only some people who ate a mushroom species manifested characteristic toxicity should not exclude the diagnosis of mushroom poisoning. The degree of toxicity may be dose related or genetically determined, or a person may have a preexistent pathologic disposition to toxicity.
10. Mushroom allergy can manifest as an anaphylactic reaction.
11. Most poisonous mushrooms resemble edible mushrooms at some phase of their growth. For this reason, even careful examination of the ring, cap, consistency, form, and color may not reliably identify the edible species. Also, characteristic features of specific toxic mushrooms may not be present under certain conditions. Although the deadly *A. phalloides* and *A. virosa* usually have remnant patches of tissue from the universal veil that envelops the mushroom in its “button” stage, rain may wash these remnants away. Similarly, a subterranean basal cup may not be noticed if the mushroom is cut at the ground level by a novice forager (Fig. 120–1).
12. Even the new in-vogue “wild mushrooms” in the specialty markets may not be entirely safe.

SUMMARY

- It is essential to determine whether the ingested mushroom is one of the high morbidity/mortality varieties such as *Amanita*.
- The onset of GI symptoms within 5 hours of ingestion excludes exposure to an *Amanita* species except for those eaten in the Pacific Northwest where *Amanita smithiana* exists.
- Several mushroom species including *Amanita smithiana* containing allenic norleucine and *Cortinarius orellanus* containing orelline and orellanine result in renal failure more than 24 hours after ingestion.
- Silibinin, the active component of the milk thistle, may modify or occupy membrane receptor sites thereby inhibiting α -amanitin hepatocellular penetration. Silibinin is not FDA approved for therapeutic intervention, but it is available in a clinical trial (Antidotes in Depth: A36).
- The grim prognosis associated with Amanitin hepatotoxicity necessitates rapid assessment by a hepatic transplantation service, even though the clinical evolution is unpredictable and criteria for transplantation under these circumstances are not established.

A36 ANTIDOTES IN DEPTH

Silibinin

Mary Ann Howland

INTRODUCTION

Silibinin is the active ingredient in milk thistle, *Silybum marianum*, purported to prevent and treat amatoxin induced liver failure. Legalon SIL is a purified silibinin derivative available via an FDA approved open treatment as an investigational new drug (IND) for IV administration in patients suspected of ingesting amatoxin containing mushrooms.

HISTORY

Milk thistle has been used since the 16th century for the treatment of liver disease. Legalon SIL has been used in Europe since 1984.

PHARMACOLOGY

Chemistry

Legalon SIL, silibinin-C-2',3-dihydrogen succinate disodium salt ($C_{33}H_{28}O_{16}Na_2$) is a microcrystalline water soluble powder for injection manufactured by Rottapharm/Madaus, a German pharmaceutical company.⁴ Silibinin is a mixture of cis- and trans diastereomers of silibinin A and B extracted from milk thistle fruit and then esterified with succinic anhydride to form the water soluble salt.

Related Compounds

The extract from the seeds of the plant milk thistle (*Silybum marianum*) contains 65% to 80% silymarin. Silymarin contains many flavonoids including silybin A and silybin B, with a 1:1 ratio making up silibinin.¹³ Silymarin is poorly water soluble with a low bioavailability, but has substantial enterohepatic cycling.

Mechanism of Action

Silibinin competitively inhibits the organic anion transporter (OATP1B3) that is responsible for the uptake and enterohepatic recycling of amatoxin. Early administration prevents initial uptake while later administration prevents enterohepatic recycling of the amatoxin.⁸ Other possible mechanisms of action include inhibition of hepatocyte TNF- α release, stimulation of mRNA protein synthesis, and antioxidant and antiinflammatory effects.

Pharmacokinetics and Pharmacodynamics

Legalon SIL is rapidly metabolized and eliminated from the blood. Precise details are not available.

ROLE IN AMANITA MUSHROOM EXPOSURE

There are no randomized clinical trials of Legalon SIL or silibinin in the treatment of amatoxin induced mushroom poisoning. Evidence for its use comes from observational studies in humans, a variety of animal studies with mixed results, and in vitro studies in cultured human hepatocytes.

Although in an experimental model of cultured canine hepatocytes silibinin was not able to reduce cytotoxicity, two experiments using cultured human hepatocytes demonstrated that the addition of silibinin was able to protect against lipid peroxidation and cytotoxicity, and also stimulate cell proliferation and attachment.⁵⁻⁷

One of the earliest animal studies was conducted in mice using sublethal doses of *Amanita phalloides* extract

administered intraperitoneally (IP) every 24 hours for 3 doses.² Silymarin was administered intravenously (IV) at 16 and 24 hours, with the highest dose resulting in a 58% survival compared to 11% in the control group. When the experiment was repeated using a purified α -amatoxin, time was the most important factor in predicting survival. All of the mice treated with silymarin one hour before exposure survived, while none survived when treatment was started 8 hours after exposure.² A similar study in mice treated with IP α -amatoxin followed 4 hours later with IP silibinin dosed every 4 to 6 hours for 48 hours was not able to show a benefit in reducing the increase in LFTs or a difference in the liver histopathology.¹¹

A study conducted in canines utilized an oral sublethal dose of *Amanita phalloides* extract and IV silymarin administered at 5 and 24 hours postingestion. Silymarin prevented or reduced the elevation in LFTs and the fall in clotting factors and reduced the severity of liver failure.³ A similar protocol, but this time using silibinin instead of silymarin, demonstrated similar biochemical findings and a 100% survival.¹²

A 20 year retrospective review of European and American case reports of over 2000 hospitalized patients with amatoxin induced mushroom poisoning concluded that silibinin alone, or in combination, and N-acetylcysteine show the most promise as hepatoprotective therapies.¹ The authors acknowledged the difficulty in determining efficacy of various therapies given the lack of randomized controlled trials. A more recent review included the data from the previous authors and any subsequent hospitalized patients in the interim. A multidimensional multivariate statistical analysis of the data reached a similar conclusion.⁹

A retrospective case series of *Amanita phalloides* poisoning from Australia and New South Wales included 10 patients with probable poisoning, 9 of whom were treated with silibinin since use began in 2005.¹⁰ Four of these patients died. Mistaken identity of the mushrooms, particularly in immigrants, and a large number of ingested mushrooms seemed associated with a higher mortality. There was often a time delay to administration of Legalon SIL due to stocking and acquisition issues.

ADVERSE EFFECTS AND SAFETY ISSUES

Since 1984, Legalon SIL has been administered to over 9000 patients with a good safety record.⁸ Mild flushing during intravenous infusion is commonly reported.

PREGNANCY AND LACTATION

There are no data available with regard to pregnancy and lactation. Administration should be based on a risk-to-benefit analysis.⁴

DOSING AND ADMINISTRATION

Efficacy is thought to be related to prompt administration following the diagnosis of amatoxin induced mushroom poisoning. The loading dose of Legalon SIL is 5 mg/kg IV infused over one hour. This should be followed by a maintenance dose of 20 mg/kg IV as a continuous infusion over 24 hours and continued until an elevated PT/INR returns to normal and LFTs have decreased significantly.⁴ Each 350 mg vial of Legalon SIL should be reconstituted with 35 mL of D₅NS. The dose should be further diluted in D₅W. For example, after reconstitution, four vials (the 24 hour maintenance dose for a 70 kg person) can be put in 500 mL D₅W and infused IV over 24 hours.

FORMULATION AND ACQUISITION

Each vial of lyophilized Legalon SIL contains 350 mg of silibinin. Legalon SIL can be obtained by a physician via an FDA sanctioned, open treatment IND by calling the 24 hour, toll-free hotline (866-520-4412). A stockpile is kept in the United States, allowing same day shipment.

SUMMARY

- Legalon SIL is a purified silibinin derivative for the prevention and treatment of amatoxin induced mushroom poisoning.
- Silibinin competitively inhibits the organic anion transporter (OATP1B3) that is responsible for the uptake and enterohepatic recycling of amatoxin.
- Silibinin should be administered as soon as possible following a presumed ingestion without waiting for mycologic confirmation.

- A 24 hour, toll-free hotline (866-520-4412) is available to obtain Legalon SIL.

121 PLANTS

Lewis S. Nelson and Lewis R. Goldfrank

Five to ten percent of all human exposures reported to poison centers involve plants. Probably because plants are so accessible and attractive to youngsters, in approximately 80% of these cases the individuals are younger than 6 years of age. As indoor plants have become ever more popular, the incidence of plant exposures has increased. Data compiled by the American Association of Poison Control Centers (AAPCC) give some indication of which plants are more commonly involved ([Chap. 136](#)), but these plants typically have relatively limited toxicity. More than 80% of patients reported to the AAPCC as being exposed were asymptomatic, less than 20% had minor to moderate symptomatology, and less than 7% necessitated a health care visit. The benignity of these exposures is represented by a fatality rate of less than 0.001%. This chapter addresses the toxicologic principles associated with the most potentially dangerous plants.

HISTORY AND CLASSIFICATION OF PLANT XENOBIOTICS

Aconitine, from monkshood, exemplifies the rich history of plant toxicology. It was believed by the Greeks to be the first poison—"lycotonum"—created by the goddess Hecate from foam of the river Cerebrus. Alkaloid constituents are responsible for its toxic (and therapeutic) effects. Alkaloids represent one of several classes of organic molecules found in plants as defined by the science of pharmacognosy, which is the science of medicines derived from natural sources. The pharmacognosy approach is consistent with the literature of plant efficacy and is applied here to their toxicity ([Table 121–1](#)). Unfortunately, the science of pharmacognosy is not always straightforward, and systems of classification may vary depending on the pharmacognosist. Hence our approach borrows primarily from two groups of authors to keep the classification as consistent as possible.^{48,120} The major groups are as follows:

TABLE 121–1. Primary Toxicity of Common Important Plant Species

<i>Plant Species (Family)</i>	<i>Typical Common Names</i>	<i>Primary Toxicity</i>	<i>Xenobiotic(s)</i>	<i>Class of Xenobiotic</i>
<i>Abrys precatorius</i> (Euphorbiaceae) ^a	Prayer beans, rosary pea, Indian bean, crab's eye, Buddhist's rosary bead, prayer bead, jequinity pea	Gastrointestinal	Abrin	Protein, lectin, peptide, amino acid
<i>Aconitum napellus</i> and other <i>Aconitum</i> spp (Ranunculaceae) ^b	Monkhood and others	Cardiac, neurologic	Aconitine and related compounds	Alkaloid
<i>Aconis calamus</i> (Araliaceae)	Sweet flag, rat root, flag root, calamus	Gastrointestinal	Acarin	Phenol or phenylpropanoid
<i>Aesculus hippocastanum</i> (Hippocastanaceae)	Horse chestnut	Hematologic	Esculetide (6-β-D-glucopyranosyloxy-7-hydroxycoumarin)	Phenol or phenylpropanoid
<i>Agave lecheguilla</i> (Amaryllidaceae)	Agave	Dermatitis, photosensitivity in animals	Aglycones, smilagenin, sarsapogenin	Saponin glycoside
<i>Aloe barbadensis</i> , <i>Aloe vera</i> , others (Liliaceae/Amaryllidaceae)	Aloagave	Gastrointestinal	Barbaloin, iso-barbaloin, aloinosides	Anthraquinone glycoside
<i>Anabaena</i> and <i>Aphanizomenon</i> ^c	Blue-green algae	Neurologic	Saxitoxin equivalents	Guanidinium compound
<i>Anacardium occidentale</i> , many others (Anacardiaceae)	Cashew, many others	Contact dermatitis	Urushiol oleoresins	Terpenoid
<i>Anthoxanthum odoratum</i> (Poaceae)	Sweet vernal grass	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Areca catechu</i> (Arecaceae)	Betel nut	Cholinergic	Arecoline	Alkaloid
<i>Argemone mexicana</i> (Papaveraceae)	Mexican pricklepoppy	Gastrointestinal	Sanguinarine	Alkaloid
<i>Argyrea nervosa</i>	Hawaiian baby woodrose seeds	Neurologic	Lysergic acid amide	Alkaloid
<i>Argyrea</i> spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
<i>Aristolochia reticulata</i> , <i>Aristolochia</i> spp (Aristolochiaceae) ^d	Texan or Red River snake root	Renal, carcinogenic	Aristolochic acid	Alkaloid relative as derivative of nothebaine
<i>Artemisia absinthium</i> (Compositaceae/ Asteraceae) ^e	Abnthe	Neurologic	Thujone	Terpenoid

<i>Asclepias</i> spp (Asclepidaceae)*	Milk weed	Cardiac	Asclepin and related cardenolides	Cardioactive steroid
<i>Astragalus</i> spp (Fabiaceae)*	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Atractylis gummifera</i> (Compositaceae)*	Thistle	Hepatic	Atractyloside, gummiferine	Glycoside
<i>Atropa belladonna</i> (Solanaceae)*	Belladonna	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Azalea</i> spp (Ericaceae)* ^a	Azalea	Cardiac, neurologic	Grayanotoxin	Terpenoid
<i>Berberis</i> spp (Ranunculaceae)	Barberry	Oxytocic, cardiovascular	Berberine	Alkaloid
<i>Blighia sapida</i> (Sapindaceae)*	Akee fruit	Metabolic, gastrointestinal, neurotoxic	Hypoglycin	Protein, lectin, peptide, amino acid
<i>Borago officinalis</i> (Boragniaceae)*	Borage	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Brassica</i> spp ^b	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Brassica nigra</i> (Brassicaceae)	Black mustard	Dermatitis, irritant	Sinigrin	Glucosinolate (isothiocyanate glycoside)
<i>Brassica oleracea</i> var. capitata	Cabbage	Metabolic (precursor to goittrin, antithyroid compound)	Progoittrin	Isothiocyanate glycoside
<i>Cactus</i> spp ^b	Cactus	Dermatitis, mechanical	Nontoxic	None
<i>Caladium</i> spp (Araceae) ^b	Caladium	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Calotropis</i> spp (Asclepidaceae)*	Crown flower	Cardiac	Asclepin and related cardenolides	Cardioactive steroid
<i>Camellia sinensis</i> (Theaceae)	Tea, green tea	Cardiac, neurologic	Theophylline, caffeine	Alkaloid

<i>Cannabis sativa</i>	Cannabis, marijuana, Indian hemp, hashish, pot	Neurologic	Tetrahydrocannabinol	Terpenoid, resin, oleoresin
<i>Capsicum frutescens</i> , <i>Capsicum annuum</i> , <i>Capsicum</i> spp (Solanaceae) ^a	<i>Capsicum</i> , cayenne pepper	Dermatitis, irritant	Capsaicin	Phenol or phenylpropanoid
<i>Cascara sagrada</i> , <i>Rhamnus purshiana</i> , <i>Rhamnus cathartica</i> (Rhamnaceae)	Cascara, sacred bark, Chittam bark, common buckthorn	Gastrointestinal	Cascarosides, O-glycosides, emodin	Anthraquinone glycoside
<i>Cassia senna</i> , <i>Cassia angustifolia</i> (Fabaceae)	Senna	Gastrointestinal	Sennosides	Anthraquinone glycoside
<i>Catha edulis</i> (Elaeagnaceae)	Khat	Cardiac, neurologic	Cathinone	Alkaloid
<i>Catharanthus roseus</i> (formerly <i>Vinca rosea</i>) (Apocynaceae)	<i>Catharanthus</i> , vinca, madagascar periwinkle	Gastrointestinal	Vincristine	Alkaloid
<i>Caulophyllum thalictroides</i> (Berberidaceae)	Blue cohosh	Nicotinic	N-Methylocytisine and related compounds	Alkaloid
<i>Cephaelis ipecacuanha</i> , <i>Cephaelis acuminata</i> (Rubiaceae) ^a	Syrup of ipecac	Gastrointestinal, cardiac	Emetine/cephaline	Alkaloid
<i>Chlorophytum comosum</i> ^b	Spider plant	Dermatitis, contact, and allergic	Ursiol oleoresins	Terpenoid
<i>Chondrodendron</i> spp, <i>Curare</i> spp, <i>Strychnos</i> spp ^c	Tubocurare, curare	Neurologic	Tubocurarine	Alkaloid
<i>Chrysanthemum</i> spp, <i>Taraxacum officinale</i> , many other Compositaceae (Asteraceae) ^b	Chrysanthemum, dandelion, other Compositaceae	Contact dermatitis	Sesquiterpene lactones	Terpenoid
<i>Cicuta maculata</i> (Aplaceae/Umbelliferae) ^a	Water hemlock	Neurologic	Cicutoxin	Alcohol
<i>Cinchona</i> spp (Rubiaceae) ^a	Cinchona	Cardiac, cinchonism	Quinine	Alkaloid
<i>Citrus aurantium</i> (Rutaceae) ^a	Bitter orange	Cardiac, neurologic	Synephrine	Alkaloid
<i>Citrus paradisi</i> (Rutaceae)	Grapefruit	Drug interactions	Bergamottin, naringenin, or naringin	Phenol or phenylpropanoid

<i>Claviceps purpurea</i> , <i>Claviceps paspali</i> (Claviceptacea – fungus) ^a	Ergot	Cardiac, neurologic, oxytocic	Ergotamine and related compounds	Alkaloid
<i>Coffea arabica</i> (Rubiaceae)	Coffee	Cardiac, neurologic	Caffeine	Alkaloid
<i>Cola nitida</i> , <i>Cola</i> spp (Sterculiaceae)	Kola nut	Cardiac, neurologic	Caffeine	Alkaloid
<i>Colchicum autumnale</i> (Liliaceae) ^a	Autumn crocus	Multi-system	Colchicine	Alkaloid
<i>Conium maculatum</i> (Apiaceae/ Umbelliferae) ^a	Poison hemlock	Nicotinic, neurologic, respiratory, renal	Conine	Alkaloid
<i>Convallaria majalis</i> ^a	Lily of the valley	Cardiac	Convallatoxin, strophanthin (~40 others)	Cardioactive steroid
<i>Coptis</i> spp (Ranunculaceae)	Goldenthread	Oxytocic, cardiovascular	Berberine	Alkaloid
<i>Crassula</i> spp ^b	Jade plant	Gastrointestinal	Nontoxic	None
<i>Crotalaria</i> spp (Fabaceae) ^a	Rattlebox	Hepatic (venoocclusive disease)	Pyrolizidine alkaloids	Alkaloid
<i>Croton tiglium</i> and <i>Croton</i> spp (Euphorbiaceae)	Croton	Carcinogen, gastrointestinal	Croton oil	Lipid and fixed oil, also contains tropane alkaloid and diterpene
<i>Cycas circinalis</i> ^a	Queen sago, india, cycad	Neurologic	Cycasin	Glycosides
<i>Cytisus scoparius</i> (Fabaceae) ^a	Broom, Scotch broom	Nicotinic, oxytocic	Sparteine	Alkaloid
<i>Datura stramonium</i> (Solanaceae) ^a	Jimson weed, stramonium, locoweed	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Delphinium</i> spp (Ranunculaceae) ^a	Larkspur, others	Cardiac, neurologic	Methyllycaconitine	Alkaloid related compounds
<i>Dieffenbachia</i> spp (Araceae) ^b	Dieffenbachia	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid

<i>Digitalis lanata</i> ^a	Grecian figglove	Cardiac	Digoxin, lanatosides A–E (contains ~ 70 cardiac glycosides)	Cardioactive steroid
<i>Digitalis purpurea</i> ^a	Purple foxglove	Cardiac	Digitoxin	Cardioactive steroid
<i>Dipteryx odorata</i> , <i>Dipteryx oppositifolia</i> (Fabaceae)	Tonka beans	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Ephedra</i> spp., especially <i>sinensis</i> (Ephedraceae/Gnetaceae – Gymnosperms) ^a	Ephedra, Ma-huang	Cardiac, neurologic	Ephedrine and related compounds	Alkaloid
<i>Epipremnum aureum</i> (Araceae) ^a	Pothos	Dermatitis, mechanical, and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Erythroxylum coca</i>	Coca	Neurologic, cardiac	Cocaine	Alkaloid
<i>Eucalyptus globus</i> or spp. ^a	Eucalyptus	Dermatitis, contact, and allergic	Eucalyptol	Terpenoid
<i>Euphorbia pulcherrima</i> , <i>Euphorbia</i> spp (Euphorbiaceae) ^a	Poinsettia	Dermatitis, contact, and allergic	Phorbol esters	Terpenoid
<i>Galium triflorum</i> (Rubiaceae)	Sweet-scented bedstraw	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Ginkgo biloba</i> (Ginkgoaceae)	Ginkgo	Dermatitis, contact, and allergic Hematologic Neurologic	Urushiol oleoresins Ginkgolides A–C, M 4-Methoxypyridoxine in seeds only	Terpenoid Terpenoid Alkaloid, pyridine
<i>Gloriosa superba</i> (Liliaceae) ^a	Meadow saffron	Multisystem	Colchicine	Alkaloid
<i>Glycyrrhiza glabra</i> ^a	Licorice	Metabolic, renal	Glycyrrhizin	Saponin glycoside
<i>Gossypium</i> spp	Cotton, cottonseed oil	Metabolic	Gossypol	Terpenoid
<i>Hedera pulegioides</i> (Lamiaceae) ^a	Pennyroyal	Hepatic, neurologic, oxytoxic	Pulegone	Terpenoid
<i>Hedera helix</i> (Araliaceae) ^a	Common ivy	Not absorbed	Hederacoside C, α-hederin, hederagenin	Cardioactive steroid
<i>Hedysarum alpinum</i> (Fabaceae)	Wild potato	Metabolic, neurologic	Swainsonine	Alkaloid

<i>Heliotropium</i> spp (Compositae/ Asteraceae) ^a	Ragwort	Hepatic (venoocclusive disease)	Pyrolizidine alkaloids	Alkaloid
<i>Helleborus niger</i> ^a	Black hellebore, Christmas rose	Cardiac	Hellebrin	Cardioactive steroid
<i>Hydrastis canadensis</i> (Ranunculaceae) ^a	Goldenseal	Neurologic, oxytocic, cardiovascular, respiratory	Hydrastine, berberine	Alkaloid
<i>Hyoscyamus niger</i> (Solanaaceae) ^a	Henbane, hyoscyamus	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Hypericum perforatum</i> (Clusiaceae)	St. John's wort	Dermatitis, photosensitivity, neurologic, hepatic drug interactions	Hyperforin, hypericin	Terpenoid
<i>Ilex paraguariensis</i> (Aquifoliaceae)	Maté, Yerba Maté, Paraguay tea	Cardiac, neurologic	Caffeine	Alkaloid
<i>Ilex</i> spp berries (Aquifoliaceae) ^b	Holly	Gastrointestinal	Mixture. Alkaloids, polyphenols, saponins, steroids, triterpenoids	Unidentified
<i>Illicium anisatum</i> (Illiciaceae) ^a	Japanese Star anise	Neurologic	Anasatin	Terpenoid
<i>Ipomoea tricolor</i> and other (<i>Ipomoea</i> spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
<i>Jatropha curcas</i> (Euphorbiaceae)	Black vomit nut, physic nut, purging nut	Gastrointestinal	Curcin	Protein, lectin, peptide, amino acid
<i>Karwinskia humboldtiana</i> ^a	Buckthorn, wild cherry, tullidora, coyatillo, capulinillo, others	Neurologic, respiratory	Toxin T-514	Phenol or phenylpropanoid
<i>Laburnum anagyroides</i> (syn. <i>Cytisus laburnum</i> ; Fabaceae) ^a	Golden chain, laburnum	Nicotinic	Cytisine	Alkaloid
<i>Lantana camara</i> (Verbenaceae)	Lantana	Dermatitis, photosensitivity	Lantadene A and B, phylloerythrin	Terpenoid

<i>Lathyrus sativus</i> *	Grass pea	Neurologic, skeletal	β -N-oxalylamino-L-alanine (BOAA); β -aminopropionitrile (BAPN)	Protein, lectin, peptide, amino acid
<i>Lobelia inflata</i> (Campanulaceae)	Indian tobacco	Nicotinic	Lobeline	Alkaloid
<i>Lophophora williamsii</i>	Peyote or mescal buttons	Neurologic	Mescaline	Alkaloid
<i>Lupinus latifolius</i> and other <i>Lupinus</i> spp (Fabaceae)	Lupin	Nicotinic	Anagrine	Alkaloid
<i>Lycopersicon</i> spp (Solanaceae)*	Tomato (green)	Gastrointestinal, neurologic, anticholinergic	Tomatidine, tomatidine	Glycoalkaloid
<i>Mahonia</i> spp (Ranunculaceae)	Oregon grape	Oxytocic, cardiovascular	Berberine	Alkaloid
<i>Mandragora officinarum</i> (Solanaceae)*	European or true mandrake	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Manihot esculenta</i> (Euphorbiaceae)*	Cassava, manihot, tapioca	Metabolic, neurotoxic, motor spastic paresis and vision disturbance with chronic use	Linamarin	Cyanogenic glycoside
<i>Medicago</i> spp (Fabaceae/Legumaceae)	Sweet clover (spoiled moldy)	Hematologic	Dicumarol	Phenol or phenylpropanoid
<i>Mentha pulegium</i> (Lamiaceae)*	Pennyroyal	Hepatic, neurologic, oxytocic	Pulegone	Terpenoid
<i>Microcystis</i> and <i>Anabaena</i> spp	Blue-green algae (cyanobacteria)	Hepatotoxic, dermatitis, photosensitivity	Microcystin	Protein, lectin, peptide, amino acid
<i>Myristica fragrans</i>	Nutmeg, pericarp = mace	Neurologic (hallucinations)	Myristicin, elemicin	Terpenoid
<i>Narcissus</i> spp and other (Amaryllidaceae, Liliaceae)	Narcissus	Dermatitis, mechanical, and cytotoxic	Lycorine, homolycorin	Alkaloid
<i>Nerium oleander</i> *	Oleander	Cardiac	Oleandrin	Cardioactive steroid
<i>Nicotiana tabacum</i> and other <i>Nicotiana</i> spp (Solanaceae)*	Tobacco	Nicotinic	Nicotine	Alkaloid
<i>Oxytropis</i> spp (Fabaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Papaver somniferum</i>	Poppy	Neurologic	Morphine/other opium derivatives	Alkaloid

<i>Paullinia cupana</i> (Sapindaceae)	Guarana	Cardiac, neurologic	Caffeine	Alkaloid
<i>Pausinystalia yohimbe</i> (Rubiaceae) ^a	Yohimbe	Cardiac, cholinergic	Yohimbine	Alkaloid
<i>Philodendron</i> spp (Araceae) ^b	Philodendron	Dermatitis, mechanical, and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Phoradendron</i> spp (Loranthaceae or Viscaceae)	American mistletoe	Gastrointestinal	Phoratoxin, ligatoxin	Protein, lectin, peptide, amino acid
<i>Physostigma venenosum</i> (Fabaceae) ^a	Calabar bean, ordeal bean	Cholinergic	Physostigmine	Alkaloid
<i>Phytolacca americana</i> (Phytolaccaceae) ^a	American cancer Pokeweed, poke	Gastrointestinal	Phytolaccotoxin	Protein, lectin, peptide, amino acid
<i>Pilocarpus jaborandi</i> , <i>Pilocarpus pinnatifolius</i> (Rutaceae) ^a	Pilocarpus, jaborandi	Cholinergic effects	Pilocarpine	Alkaloid
<i>Piper methysticum</i> ^a	Kava kava	Hepatic, neurologic	Kawain, methysticine yangonin, other kava lactones	Terpenoid, resin, and oleoresin
<i>Plantago</i> spp	Plantago (seed husks)	Gastrointestinal	Psyllium	Carbohydrate
<i>Podophyllum emodi</i> (Berberidaceae) ^a	Wild mandrake	Multisystem	Podophyllin (lignan)	Phenol or phenylpropanoid
<i>Podophyllum peltatum</i> (Berberidaceae) ^a	Mayapple	Multisystem	Podophyllin (lignan)	Phenol or phenylpropanoid
<i>Populus</i> spp (Salicaceae)	Poplar species	Salicylism	Salicin	Glycoside
<i>Primula obconica</i> (Primulaceae)	Primrose	Dermatitis, contact, allergic	Primin	Phenol or phenylpropanoid
<i>Prunus americana</i> , <i>Prunus</i> spp, <i>Malus</i> spp (Rosaceae) ^a	Apricot seed pits, wild cherry, peach plum, pear, almond, apple, and other seed kernels	Metabolic, acidosis, respiratory failure, coma, death	Amygdalin, emulsin	Cyanogenic glycoside

<i>Pteridium</i> spp (Polypodiaceae)	Bracken fern	Carcinogen, thiaminase	Ptaquiloside	Terpenoid
<i>Pulsatilla</i> spp (Ranunculaceae)	Pulsatilla	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
<i>Quercus</i> spp	Oak	Metabolic, livestock toxicity	Tannic acid	Phenol or phenylpropanoid
<i>Ranunculus</i> spp (Ranunculaceae)	Buttercups	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
<i>Rauwolfia serpentine</i> (Apocynaceae)	Indian snakeroot	Cardiac, neurologic	Reserpine	Alkaloid
<i>Remijna pedunculata</i> (Rubiaceae) ⁴	Cuprea bark	Cardiac, cinchonism	Quinine	Alkaloid
<i>Rhamnus frangula</i> (Rhamnaceae)	Frangula bark, alder buckthorn	Gastrointestinal	Frangulins	Anthraquinone glycoside
<i>Rheum officinale</i> , <i>Rheum</i> spp (Polygonaceae)	Rhubarb	Gastrointestinal Metabolic	Rhein anthrones Oxalic/Acid (soluble)	Anthraquinone glycoside Carboxylic acid
<i>Rheum</i> spp (Polygonaceae)	Rhubarb species	Urologic	Oxalates	Carboxylic acid
<i>Rhododendron</i> spp (Ericaceae) ⁴	Rhododendron	Cardiac, neurologic	Grayanotoxins	Terpenoid including resin and oleoresin
<i>Ricinus communis</i> (Euphorbiaceae) ²	Castor or rosary seeds, purging nuts, physic nut, tick seeds	Gastrointestinal	Ricin, curcin	Protein, lectin, peptide, amino acid
<i>Robinia pseudoacacia</i> (Fabaceae) ⁴	Black locust	Gastrointestinal	Robin (robinia lectin)	Protein, lectin, peptide, amino acid
<i>Rumex</i> spp (Polygonaceae)	Dock species	Urologic	Oxalates	Carboxylic acid
<i>Salix</i> spp (Salicaceae)	Willow species	Salicylum	Salicin	Glycosides, other
<i>Sambucus</i> spp (Caprifoliaceae)	Elderberry	Metabolic	Anthracyanins	Cyanogenic glycoside
<i>Sanguinaria canadensis</i> (Papaveraceae)	Sanguinaria, bloodroot	Gastrointestinal	Sanguinarine	Alkaloid
<i>Schefflera</i> spp (Araceae) ³	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Schlumbergera bridgesii</i> ⁴	Christmas cactus	Dermatitis, mechanical	Nontoxic	None

<i>Senecio</i> spp (Compositae/Asteraceae) ^a	Groundsel	Hepatic (venoocclusive disease)	Pyrolizidine alkaloids	Alkaloid
<i>Sida carpinifolia</i> (Malvaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Sida cordifolia</i> (Malvaceae) ^a	Bala	Cardiac, neurologic	Ephedrine and related compounds	Alkaloid
<i>Solanum americanum</i> (Solanaceae) ^a	American nightshade	Gastrointestinal, neurologic, anticholinergic	Solasodine, soladulcidine, solanine, chaconine	Glycoalkaloid
<i>Solanum dulcamara</i> (Solanaceae) ^{a,b}	Bittersweet woody nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids	Alkaloid
<i>Solanum nigrum</i> (Solanaceae) ^a	Black nightshade, common nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids	Alkaloid
<i>Solanum tuberosum</i> (Solanaceae) ^a	Potato (green), leaves	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine	Alkaloid
<i>Spathiphyllum</i> spp (Araceae) ^b	Peace lily	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Spinacia oleracea</i> (Chenopodiaceae)	Spinach, others	Urologic	Oxalates	Carboxylic acid
<i>Strychnos nux-vomica</i> , <i>Strychnos ignatia</i> (Loganiaceae) ^a	Nux vomica, Ignatia, St. Ignatius bean, vomit button	Neurologic	Strychnine, brucine	Alkaloid
<i>Swainsonia</i> spp (Fabaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Symphytum</i> spp (Boraginaceae) ^a	Comfrey	Hepatic (venoocclusive disease)	Pyrolizidine alkaloids	Alkaloid
<i>Tanacetum vulgare</i> (= <i>Chrysanthemum vulgare</i> ; Compositaceae/Asteraceae) ^a	Tansy	Neurologic	Thujone	Terpenoid
<i>Taxus baccata</i> , <i>Taxus brevifolia</i> , other <i>Taxus</i> spp (Taxaceae) ^a	English yew, Pacific yew, yew	Cardiac	Taxine	Alkaloid

<i>Theobroma cacao</i> (Sterculiaceae)	Cocoa	Cardiac, neurologic	Theobromine	Alkaloid
<i>Thevetia peruviana</i> ^a	Yellow oleander	Cardiac	Thevetin	Cardioactive steroid
<i>Toxicodendron radicans</i> , <i>Toxicodendron toxicarium</i> , <i>Toxicodendron diversilobum</i> , <i>Toxicodendron vernix</i> , <i>Toxicodendron</i> spp. many others (Anacardiaceae) ^a	Poison ivy, poison oak, poison sumac	Dermatitis, contact and allergic	Urushiol oleoresins	Terpenoid
<i>Tribulus terrestris</i> (Fabaceae)	Caltrop, puncture vine	Dermatitis, photosensitivity in animals	Steroidal saponins (aglycones, diosgenin, yamogenin)	Saponin glycoside
<i>Trifolium pratense</i> and other (Fabaceae/ Legumaceae)	Red clover	Phytoestrogen hematologic	Formononetin, Biochanin A coumarin	Phenol (isoflavone)
<i>Tussilago farfara</i> (Compositae/ Asteraceae) ^a	Coltsfoot	Hepatic (venoocclusive disease)	Pyrolizidine alkaloids	Alkaloid
<i>Urginea maritima</i> , <i>Urginea indica</i> ^a	Red, or Mediterranean squill, Indian squill, sea onion	Cardiac	Scillaren A, B	Cardioactive steroid
<i>Veratrum viride</i> , <i>Veratrum album</i> , <i>Veratrum californicum</i> (Liliaceae) ^a	False hellebore, Indian poke, California hellebore	Cardiac	Veratridine	Alkaloid
<i>Vicia faba</i> , <i>Vicia sativa</i> (Fabaceae)	Fava bean, vetch	Hematologic	Vicine, convicine	Glycoside
<i>Viscum album</i> (Loranthaceae or Viscaceae)	European mistletoe	Gastrointestinal	Viscumin	Protein, lectin, peptide, amino acid, lignan, polypeptide
<i>Wisteria floribunda</i> (Fabaceae)	Wisteria	Gastrointestinal	Cystatin	Protein, lectin, peptide, amino acid

^a Reports of life-threatening effects from plant use. ^b Plants reported commonly among calls to poison centers.

1. Alkaloids: Molecules that react as bases and contain nitrogen, usually in a heterocyclic structure. Alkaloids typically have strong pharmacologic activity that defines many major toxidromes.
2. Glycosides: Organic compounds that yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The aglycone is the basis of subclassification into saponin or steroidal glycosides (including steroidal cardiac glycosides, cyanogenic glycosides, anthraquinone glycosides), and others such as atractyloside and salicin.
3. Terpenes and resins: Assemblages of five-carbon units (isoprene unit) with many types of functional groups (eg, alcohols, phenols, ketones, and esters) attached. This is the largest group of secondary metabolites; approximately 20,000 are identified. Most essential oils are mixtures of monoterpenes, and the terpene name depends on the number of isoprene assemblages. Monoterpenes have two units (C₁₀H₁₆), sesquiterpenes have three isoprene units (C₁₅), diterpenes have four isoprene units (C₂₀), and triterpenes have six (C₃₀). These molecules often play an active role in plant defense mechanisms.
4. Proteins, peptides, and lectins: Proteins consist of amino acid units with various side chains, and peptides consist of linkages among amino acids. Lectins are glycoproteins classified according to the number of protein chains linked by disulfide bonds and by binding affinity for specific carbohydrate ligands, particularly galactosamines. The toxalbumins (eg, ricin) are lectins. These components tend to be neurotoxins, hemagglutinins, or cathartics.
5. Phenols and phenylpropanoids: Phenols contain phenyl rings and have one or more hydroxyl groups attached to the ring. Phenylpropanoids consist of a phenyl ring attached to a propane side chain. These compounds are devoid of nitrogen, even though some are derived from phenylalanine and tyrosine. They constitute a major group of secondary metabolites and among plant toxins include coumarins (lactone side chains), flavonoids (built upon a flavan 2,3-dihydro-2-phenylbenzopyran nucleus, such as naringenin and rutin), lignans (two linked phenylpropanoids, such as podophyllin), lignins (complex polymers of lignans that bind cellulose for woody bark and stem), and tannins (polymers that bind to protein and can be further hydrolyzed or condensed).

Plant chemistry is complex. The simplified presentation of one xenobiotic per plant per symptom group used in [Table 121-1](#) overlooks the fact that plants contain multiple xenobiotics that work independently or in concert. Additionally, different plant families may contain similar, if not identical, xenobiotics (either from conservation of biochemical pathways inherited from a common ancestor or through convergent evolution). In some cases, xenobiotics remain unidentified and are grouped in the section Unidentified Toxins.

Dissimilar molecules from diverse pharmacognosy classes that share effects are grouped together for pragmatic purposes in the section Effects Shared Among Different Classes of Xenobiotics. They are further categorized into plant–xenobiotic interactions, sodium channel effects, antimitotic alkaloids and resins, and plant-induced dermatitis.

Our focus is on exposures to flowering plants (angiosperms) related to foraging, dietary, or occupational contact, except for some gymnosperms or algae and, rarely, medicinal contact (medicinal use as herbals is discussed in Chap. 45).⁸³ Because our understanding of plant xenobiotics is poor relative to that of pharmaceuticals, animal research is included to provide a more comprehensive foundation for comparison with human experiences that may otherwise go unrecognized without such precedent, or may likewise prove ultimately incorrect. The science of plant toxicology formally began in the United States as a response to significant poisonings of livestock. The overall quality of literature for human exposures is poor and primarily available as case reports. Many of these cases lack clear links between toxin exposure and illness, and qualitative or quantitative analyses are generally unavailable. Uncertainty is compounded by the fact that plants themselves are inherently variable, and potency and type of xenobiotic depend on the season, geography, growing environment, plant part, and methods of processing.

IDENTIFICATION OF PLANTS

Positive identification of the plant species should be attempted whenever possible, especially when the patient becomes symptomatic. Communication with an expert botanist, medical toxicologist, or poison center is highly recommended and can be facilitated by transmission of digital images or a fax.¹⁴⁸ Provisionally, simple comparison of the species in question with pictures or descriptions from a field guide of flora may help exclude the identity of the plant from among the most life threatening in Table 121–1. A plant identification can also be compared with those searched in the PLANTOX database (<http://www.accessdata.fda.gov/scripts/plantox/index.cfm>) managed by the Food and Drug Administration (FDA). To date, with some exceptions laboratory analysis is generally not timely enough to be useful except as a tool in an investigatory or forensic analysis. As the state of analytical science advances, however, it may soon be possible to confirm a diagnosis once a preliminary hypothesis based on botanical identification or symptomatology has been made.

In cases where expert identification cannot be immediately achieved, preliminary recognition of taxonomic families of poisonous plants is the simplest first step to identify or exclude poisonous plants, but it is most easily achieved when the plant is in flower or fruit. For instance, if the flower is described or looks like a flower from a tomato or potato, it probably is in the Solanaceae family. Plants of this family typically produce gastroenteric or anticholinergic findings following ingestion. It then would be appropriate to consider management with a specific antidote such as physostigmine. This approach will be less useful for xenobiotics such as pyrrolizidine alkaloids that occur in numerous different families.

APPROACH TO THE EXPOSED PATIENT AND UNDERSTANDING RISK

Identified plant species most frequently reported to poison centers are indicated in Table 121–1. In most cases, these species provide reassurance because most exposures result in benign outcomes, and only a few among these are regularly life-threatening depending on the circumstances of the exposure. Given the relatively poor understanding of toxins and in the absence of complete information about an exposure, expectant management and supportive care are the rule. Even if a plant is not marked as life threatening or commonly reported, the patient should undergo a period of observation and follow-up, given the relatively immature science of plant toxicology relative to that of pharmaceuticals.

The difficult task in human plant toxicology is the lack of adequate data to determine risk (Chap. 130). Typically, evaluations of risk are based on poison center data and usually cite the numerous calls without clinical consequence as a part of the risk equation (Chap. 136). However, poison center data are predominantly unconfirmed exposures and cases with unsubstantiated clinical manifestations (Chap. 136). These cases often represent small or nonexistent exposures, and their inclusion in the database may mask actual risks by diluting hazardous exposures with trivial or nonexistent exposures.⁶⁴ Furthermore, misidentification of the plant may occur because of either similar appearance or similar nomenclature.

In summary, basic decontamination and supportive care should be instituted as appropriate for the clinical situation and with poison center consultation. The most consequential and dangerous plant xenobiotics for humans are discussed here, and those that can produce life-threatening signs acutely are denoted in Table 121–1.

Potential symptoms listed in Table 121–1 are organized by plant name and the associated major organ system effects for quick reference as to the type of symptoms and their potential for morbidity or mortality. For instance, life-threatening symptoms such as dysrhythmias or seizures can be searched by “cardi-” or “neuro-” in the third column and compared with the plant(s) in question. The plants and xenobiotics that present life-threatening symptoms are so noted. Exposures associated with one of these plants or xenobiotics or major organ system symptoms dictate the need for possible prompt gastric emptying, decontamination, individualized therapy, and hospitalization. Nonspecific symptoms such as nausea and vomiting are listed only when they are a major cause of morbidity or mortality (toxalbumins such as ricin), but nausea and vomiting are exceptionally common in those individuals with consequential acute poisonings.

TOXIC CONSTITUENTS IN PLANTS, TAXONOMIC ASSOCIATIONS, AND SELECTED SYMPTOMS

Alkaloids

The term alkaloid refers to nitrogen-containing basic xenobiotics of natural origin. They figure prominently in the history of human–plant interaction, ranging from epidemics of poisoning caused by ergot-infected rye bread in the Middle Ages to dependency on cocaine, heroin, and nicotine in contemporary time. Numerous examples of toxic constituents of these families are given in the following discussion, which begins with a description of the major toxidromes that involves alkaloids. See also Sodium Channel Effects under Effects Shared Among Different Classes of Xenobiotics later in this chapter for descriptions of additional life-threatening alkaloids.

Anticholinergic: Belladonna Alkaloids. The belladonna alkaloids are from the family Solanaceae and the plants can be identified as members of this family by their characteristic flowers (most familiar from nightshade, potato, or tomato flowers). The belladonna alkaloids have potent antimuscarinic effects, manifested by tachycardia, hyperthermia, dry skin and mucous membranes, skin flushing, diminished bowel sounds, urinary retention, agitation, disorientation, and hallucinations (Chap. 3). Since the 1970s, the quest for recreational “highs” has surpassed unintentional ingestions as the main source of toxicity.¹⁴³ Hallucinatory effects are sought in seeds and teas, especially in late summer, when jimsonweed (*Datura stramonium*) seeds (Fig. 121–1) become available. One hundred of these seeds contain up to 6 mg atropine and related alkaloids, and an ingestion of this amount can be fatal¹⁸

FIGURE 121–1. Jimsonweed (*Datura stramonium*) initially has a showy white tubular flower which becomes a prickly fruit (pod) following maturation. Inset: The pod (inset) of Jimsonweed holds multiple small seeds containing atropine and scopolamine. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Although several anticholinergic alkaloid-containing species and even individual plants within species contain differing concentrations of several different phytochemicals, the clinical manifestations usually are similar. The onset of symptoms typically occurs 1 to 4 hours postingestion, and more rapidly if the plants are smoked or consumed as a brewed tea. The duration of effect is partly dose dependent and may last from a few hours to days.²³ The course of anticholinergic poisoning is not substantially altered by the use of physostigmine, though this may be life-saving in patients with seizures or an agitated delirium (Antidotes in Depth: A9).^{40,127} Although methods for detection of atropine and scopolamine in clinical specimens are improving, anticholinergic toxicity may be observed without detectable atropine, scopolamine, or hyoscyamine concentrations in biological fluids.

Solanine and chaconine are glycoalkaloids contained in many members of the Solanaceae family, but they are structurally and pharmacologically dissimilar to the belladonna alkaloids. The aglycone solanidine, which lacks the sugar moiety, is a steroidal alkaloid. Solanine inhibits cholinesterase in vitro, although cholinergic symptoms are not noted clinically. Nonetheless, reports of solanine-induced central nervous system (CNS) toxicity include hallucinations, delirium, and coma.¹³⁸ However, most symptomatic patients typically develop nausea, vomiting, diarrhea, and abdominal pain that begins 2 to 24 hours after ingestion, which, like CNS toxicity, may persist for several days. Although solanine is present in most of the 1700 species in the genus *Solanum*, solanine toxicity in humans is rarely encountered. The content of glycoalkaloids in tubers is usually 10 to 100 mg/kg and the maximum concentrations do not exceed 200 mg/kg. Green potatoes and the green potato plant itself are most commonly associated with symptoms, which is not surprising because the alkaloids are most concentrated in those items. The ingestion of 1 to 3 mg of glycoalkaloid per kilogram of body weight is likely to produce clinical symptoms.¹²⁵ Most reports of death come from the older literature,² and consumption of 2 to 5 g

of green components of potatoes per kilogram of body weight per day is not predicted to cause acute toxicity.¹¹³

Nicotine and Nicotineline Alkaloids: Nicotine, Anabasine, Lobeline, Sparteine, N-Methylcytisine, Cytisine, and Coniine. Nicotine toxicity (other than from inhaled sources) occurs via ingestion of leaves of *Nicotiana tabacum*, cigarettes and their remains, e-cigarette refill, organic insecticidal products, and transdermally among farm workers harvesting tobacco (green tobacco sickness)¹⁵ (Chap. 85). A topical folk remedy made from the leaf of *Nicotiana glauca* (tree tobacco) caused anabasine toxicity in an infant¹⁰⁵ The alkaloidal form of nicotine and anabasine are pale yellow oils at room temperature and readily penetrate the intact dermis. A dose of nicotine as small as 1 mg/kg of body weight can be lethal although it is more likely with doses > 4 mg/kg⁹³ Overstimulation of the nicotinic receptors by high doses of the alkaloid produces nicotinism, a toxidrome that progresses from gastrointestinal (GI) symptoms to diaphoresis, mydriasis, fasciculations, tachycardia, hypertension, hyperthermia, seizures, respiratory depression, muscle weakness, and death (Chap. 84). Wearing of protective clothing is essential for tobacco farm workers to prevent green tobacco sickness⁶

These manifestations are also produced by alkaloids other than nicotine. There are no recent reports of nicotinic toxicity from lobeline (found in all parts of *Lobelia inflata*), although its use in the 18th century resulted in morbidity and mortality.

Sparteine from broom (*Cytisus scoparius*) and N-methylcytisine from blue cohosh (*Caulophyllum thalictroides*)¹¹⁶ are examples of alkaloids that produce nicotineline effects. Laburnum or golden chain (*Cytisus laburnum*) contains cytisine, which reportedly is responsible for mass poisonings and fatalities in children and adults who eat the plants or parts thereof (even as little as 0.5 mg/kg, or a few peas).¹⁰³ Unfortunately, such reports have resulted in thousands of unnecessary hospital admissions for patients without morbidity and mortality after ingestion of this plant, demonstrating the difficulty in separating hazard from risk and in obtaining accurate dose–response information in the setting of plant exposures and human variability.

The most famous description of the end stages of nicotinic toxicity dates from approximately 2400 years ago by an observer of Socrates' fatal ingestion of a decoction of poison hemlock (*Conium maculatum*).¹¹⁷

... the person who had administered the poison went up to him and examined for some little time his feet and legs, and then squeezing his foot strongly asked whether he felt him. Socrates replied that he did not and said to us when the effect of the poison reached his heart, Socrates would depart.

Birds do not experience coniine toxicity but provide a vector for poisoning. According to the book of Exodus, quail that fed on seeds (presumably from poison hemlock) became toxic and passed the toxicity on to the Israelites who ate the fowl.¹⁶ In the 20th century, this is especially well documented in Italy, where the toxic alkaloid coniine was detected in bird meat, as well as in the blood, urine, and tissue of some individuals.¹³¹

The age of the plant seems to be directly correlated with increasing concentrations of coniine, whereas the toxin γ -coniceine occurs in greater amounts in new growth; hence, the plant remains toxic over the entire growing season. Fatal poisonings are reported on multiple continents frequently resulting from respiratory arrest. Of 17 poisoned Italian patients, all had elevated liver aminotransferases and myoglobin concentrations, and five had acute tubular necrosis.¹¹⁹ Death developed 1 to 16 days following ingestion.

Cholinergic Alkaloids: Arecoline, Physostigmine, and Pilocarpine. Betel chewing has been a habitual practice in the East since ancient times. The “quid” consists of betel nut (*Areca catechu*) and other ingredients. The effects of acute exposure to arecoline, the major alkaloid, include sweating, salivation, hyperthermia, and rarely death⁵⁵ Prolonged use is linked to dental decay and oral cancer. Physostigmine is an alkaloid derived from the Calabar bean (*Physostigma venenosum*), where it is present in concentrations of 0.15% (Antidotes in Depth: A9). Pilocarpine is derived from *Pilocarpus jaborandi* from South America. Its stimulatory effects on muscarinic receptors have proven valuable in the treatment of glaucoma. Reversal of toxicity can be achieved by atropine.

Psychotropic Alkaloids: Lysergic Acid and Mescaline. Hallucinations from the direct serotonin effects of lysergic acid alkaloids and its derivatives, and from the amphetamineline serotonin effects of the mescaline alkaloids, are reported following ingestion of morning glory seeds (*Ipomoea* spp) and peyote cactus (*Lophophora williamsii*), respectively (Chap. 82). Despite their chemical relatedness to LSD, molecules such as lysergic acid amide and lysergic acid ethylamide, found in Hawaiian baby woodrose seeds (*Argyrea nervosa*), produce findings that may appear anticholinergic¹⁷

Alkaloidal Central Nervous System Stimulants and Depressants: Ephedrine, Synephrine, Cathinone, and Opioids. The use of ephedrine-containing *Ephedra* spp in herbal dietary supplement products was banned by the FDA in 2004 because of the associated cardiovascular toxicity and deaths. Varieties of *Sida cordifolia* also contain ephedrine. Synephrine, a xenobiotic structurally related to ephedrine, occurs in bitter orange (*Citrus aurantium*), which is ingested as a plant, in foods such as marmalades, as a dietary supplement, or as a traditional medicine. Deaths and drug interactions can ensue from their use. Although illegal in the United States, another plant ingested for its CNS stimulant activity is khat (*Catha edulis*). The plant contains cathinone (α -aminopropiophenone) and cathine [(+)-norpseudoephedrine]. In addition, opioids derived from the poppy plant (*Papaver* spp) are prototypic CNS depressants and analgesics (Chap. 38).

Pyrrolizidine Alkaloids. Pyrrolizidine alkaloids are widely distributed both botanically and geographically. Approximately half of the 350 different pyrrolizidine alkaloids characterized to date are toxic when ingested. Pyrrolizidine alkaloids are found in 6000 plants and in 13 plant families, but they are most heavily represented within the Boraginaceae, Compositae, and Fabaceae families. Within these families, the genera *Heliotropium*, *Senecio*, and *Crotalaria*, respectively, are particularly notable for their content of toxic pyrrolizidine alkaloids, including the unsaturated 1-hydroxymethyl pyrrolizidine⁵⁶ The hepatic cytochrome P450 (CYP) system converts these compounds to highly reactive pyrroles in vivo. Chronic exposures stimulate the proliferation of the intima of hepatic vasculature and result in hepatic venoocclusive disease (HVOD). Poisonings occur as a result of the use of pyrrolizidine-rich plants for medicinal purposes and by contamination of food grain with seeds of pyrrolizidine-alkaloid-containing plants⁴⁴ Acute hepatocellular toxicity can occur following ingestion of 10 to 20 mg of pyrrolizidine alkaloid and is probably caused by an oxidant effect producing hepatic necrosis. An estimated 20% of patients with acute pyrrolizidine alkaloid poisoning die, 50% recover completely, and the rest develop subacute or chronic manifestations of HVOD. Pyrrolizidine alkaloids are teratogenic and are also transmitted through breast milk. Pyrrolizidine alkaloids may be present in bee pollen and have been reported in honey. Other types of plant-associated hepatic disorders are discussed in Effects Shared Among Different Classes of Xenobiotics.

Isoquinoline Alkaloids: Sanguinarine, Berberine, and Hydrastine. Adverse effects on human health due to consumption of edible mustard oil adulterated with argemone oil have been reported. Sanguinarine was detected in 26 family members who consumed a mustard oil contaminated with seeds of Mexican prickly poppy *Argemone Mexicana*¹³⁶ All patients suffered GI distress followed by peripheral edema (dropsy), skin darkening, erythema, skin lesions, perianal itching, anemia, and hepatomegaly. Ascites developed in 12%, and myocarditis and congestive heart failure occurred in approximately a third of affected individuals. Alterations in redox potentials and antioxidants in plasma may be responsible for the histopathological changes, including swollen hepatocytes and fluid accumulation in the spaces of Disse and Kupffer cell hyperplasia¹⁰ Medicinally, sanguinarine is used for dental hygiene⁹⁹ In North America, sanguinarine is found in blood root *Sanguinaria canadensis*), which, like *Argemone*, is in the Ranunculaceae family.

Berberine is structurally similar to sanguinarine and reportedly also has cardiac depressant effects. A number of medicinal plants contain berberine, including goldenseal (*Hydrastis canadensis*), Oregon grape (*Mahonia* spp), and barberry (*Berberis* spp). It causes myocardial and respiratory depression and contraction of smooth muscle vasculature and the uterus. Strychninelike movement disorders are described following ingestion of hydrastine, which makes up 4% of goldenseal.

Other Alkaloids: Emetine/Cephaline, Strychnine/Curare, and Swainsonine. Emetine and cephaline are derived from *Cephaelis ipecacuanha*, a tropical plant native to the forests of Bolivia and Brazil. They are the principal active constituents in syrup of ipecac, which produces emesis. Chronic use of syrup of ipecac, typically by patients with eating disorders or Munchausen syndrome by proxy, can lead to cardiomyopathy, smooth muscle dysfunction, myopathies, electrolyte and acid-base disturbances related to excessive vomiting, and death (Antidotes in Depth: A1). Poisoning in patients ingesting plant material is not reported.

Curare was used as an arrow poison derived from plants of the genus *Strychnos* as well as *Chondrodendron*, but the plants and their phytochemicals produce very different clinical effects. The convulsant alkaloids strychnine and brucine are found in various members of the genus *Strychnos*. Although used to produce arrow poison, the more widespread use of *Strychnos* spp in Africa was for trial by ordeal.¹¹² The seeds of *Strychnos nux-vomica* are especially rich in strychnine, which causes muscular spasms and rigidity by antagonizing glycine receptors in the spinal cord and brainstem. The plant is used as an herbal remedy for arthritis pain called “maqianzi,” which if improperly processed produces muscle spasm and weakness, including respiratory muscles (Chap. 112).

Curare is an extract of the bark of *Chondrodendron tomentosum* and certain members of the genus *Strychnos*. The physiologically active xenobiotic of curare from *Chondrodendron* is d-tubocurarine chloride, a competitive antagonist of acetylcholine at nicotinic receptors in the neuromuscular junction. Curare is the molecule from which most nondepolarizing neuromuscular blockers are derived (Chap. 68). Plant poisoning is recorded solely with its traditional use as a hunting poison.

Swainsonine has been isolated from *Swainsonia canescens*, *Astragalus lentiginos* (spotted locoweed), *Sida carpinifolia*, other species of *Swainsonia* and *Astragalus*, as well as several species in the genera *Oxytropis* and *Ipomoea*, and several fungi. After subsisting on seeds containing swainsonine for nearly 4 months, a naturalist forager manifested profound muscular weakness and died in the wilderness.⁷⁷ The compound is teratogenic and causes chronic neurologic disease called “locoism,” with weakness and failure to thrive in livestock. Swainsonine inhibits the glycosylation of glycoproteins by α -mannosidase II of the Golgi apparatus, resulting in a lysosomal storage disease. Adverse effects included hepatic, pancreatic, and respiratory manifestations, as well as lethargy and nausea.

Glycosides

Glycosides yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The nonsugar or aglycone group determines the subtype of glycoside. For instance, the cardiac glycosides have saponin

(steroid) aglycone groups and are placed among the saponin glycosides.

Saponin Glycosides: Cardiac Glycosides, Glycyrrhizin, and Ilex Saponins. Poisoning by virtually all cardioactive steroidal glycosides is clinically indistinguishable from poisoning by digoxin (Chap. 64), which itself is a cardioactive steroid derived from *Digitalis lanata*. However, compared with toxicity from pharmaceutical digoxin, toxicity resulting from the cardioactive steroidal glycosides found in plants has markedly different pharmacokinetic characteristics. For example, digitoxin in *Digitalis* spp has a plasma half-life as long as 192 hours (average 168 hours).

The pharmacologic properties are true across taxonomic boundaries. Poisonings by *Digitalis* spp,^{115,137} squill (*Urginea* spp),¹⁵⁰ lily of the valley,³ oleander (*Nerium* spp),¹⁵⁶ yellow oleander (*Thevetia* spp),⁴¹ and *Cerbera manghas*⁴² are clinically similar (Fig. 121–2). The potency of these effects depends on the specific cardioactive glycoside constituents and their dose. For instance, lily of the valley is rarely associated with morbidity or mortality, whereas ingestion of only two seeds of yellow oleander by adults can produce severe symptoms, and expected outcome is grave with several more.⁴¹ Poisonings by oleander and yellow oleander occur predominantly in the Mediterranean and in the Near and Far East. These two plants are popular attractive ornamentals and commonly result in poisoning in the United States and Europe.

FIGURE 121–2. Saponin-glycoside containing plants: (A) Lily of the valley (*Convallaria majalis*) contains the cardioactive steroid convallatoxin. (B) Yellow oleander (*Thevetia peruviana*) contains a cardioactive steroid, thevetin. (Used with permission of Darren Roberts, M.D.)

Patients experience vomiting within several hours, followed by hyperkalemia, cardiac conduction delays, and increased automaticity (bradycardia and tachydysrhythmias). Interestingly, the cardiac manifestations may be difficult to distinguish from those produced by plants containing sodium channel blockers (section Sodium Channel Effects). Activated charcoal was beneficial in preventing death after suicide attempts with yellow oleander in Sri Lanka, and its use should not be delayed in the face of uncertain plant identity.³⁶ Antibody therapy reduces mortality threefold from yellow oleander poisoning but is too expensive for developing countries where oleander-induced mortality is highest.⁴³ In addition, various cardioactive steroids respond differently to therapeutic use of digoxin-specific antibody fragments. Use of very large doses of digoxin-specific antibody (up to 37 vials reported in one case¹¹⁸) may be necessary to capitalize on the therapeutic cross-reactivity between digoxin-specific antibody and the nondigoxin cardioactive steroids, such as oleander.¹²⁶ The potential for success should lead to use of antibody therapy without delay when available. Similarly, there is variable

cross-reactivity among the individual plant cardioactive steroids with regard to the degree to which each elevates diagnostic polyclonal digoxin assay measurements in clinical laboratories.³³ These measurements can be used only as qualitative proof of exposure but not as quantitative indicators of the exposure because the elevations can result in marked underestimation of the “functional digoxin concentrations.” Until additional technologic advances occur, any positive digoxin concentration following exposure to a plant should be assumed to be significant.

Glycyrrhizin. Glycyrrhizin is a saponin glycoside derived from *Glycyrrhiza glabra* (licorice) and other *Glycyrrhiza* spp. Glycyrrhizin inhibits 11- β -hydroxysteroid dehydrogenase, an enzyme that converts cortisol to cortisone. When large amounts of licorice root are consumed chronically, cortisol concentrations rise, resulting in pseudo-hyperaldosteronism because of its affinity for renal mineralocorticoid receptors.⁵⁰ Chronic use eventually leads to hypokalemia with muscle weakness, sodium and water retention, hypertension, and dysrhythmias.¹⁶⁵ Assessment involves evaluation of the patient’s fluid and electrolytes, and electrocardiogram. Potassium replacement is the most common necessary intervention.

Ilex Species. Holly berries from more than 300 *Ilex* spp are commonly ingested by children, especially during winter holidays. They contain a mixture of alkaloids, polyphenols, saponin glycosides, steroids, and triterpenes. Saponin glycosides appear to be responsible for GI symptoms such as nausea, vomiting, diarrhea, and abdominal cramping that result from ingestion of the berries. CNS depression was reported in a case in which a child consumed a “handful” of berries; however, this child was also treated with syrup of ipecac.¹²² The toxic quantity is undefined, but it is typically suggested that no untoward effects are to be expected for ingestions of fewer than six berries. Symptoms may be expected to be restricted to GI effects, and treatment is supportive.

Cyanogenic Glycosides: (S)-Sambunigrin, Amygdalin, Linamarin, and Cycasin. Cyanogenic glycosides yield hydrogen cyanide on complete hydrolysis. These glycosides are represented in a broad range of plant species.¹⁵³ The species that are most important to humans are cassava (*Manihot esculenta*), which contains linamarin, and *Prunus* spp, which contain amygdalin.¹² Cycad toxins are neurotoxic or pseudocyanogenic. Rare reports of cyanide poisoning associated with (S)-sambunigrin in European elderberry *Sambucus nigra*; sambunigrin) are more severe when these ingestions include leaves as well as berries.²²

Many North American species of plants contain cyanogenic compounds, including ornamental *Pyracantha*, *Passiflora*, and *Hydrangea* spp, which either do not release cyanide or are rarely consumed in quantities sufficient to result in toxicity. On the other hand, although the fleshy fruit of *Prunus* spp in the Rosaceae are nontoxic (apricots, peaches, pears, apples, and plums), the leaves, bark, and seed kernels contain amygdalin, which is metabolized to cyanide. Sufficient cyanide can be absorbed to cause acute poisoning.¹⁴⁵ Amygdalin was the active ingredient of Laetrile, an apricot pit extract promoted in the 1970s for its supposed selective toxicity to tumor cells. Its sale was restricted in the United States because it lacked efficacy and safety.^{98,100} However, patients went to other countries for Laetrile therapy, which was marketed as “vitamin B-17” and was available through alternative medicine providers. The manifestations of cyanide poisoning and treatment involving use of the cyanide antidote kit are detailed elsewhere (**Chap. 126**) (Antidotes in Depth: A39–A41).

Acute and chronic cyanide toxicity (including deaths) associated with consumption of inadequately prepared cassava (*M. esculenta*) are reported worldwide (**Chap. 126**).¹ Chronic manifestations include visual disturbances (amblyopia), upper motor neuron disease with spastic paraparesis, and hypothyroidism. These findings are associated with protein-deficient states and the use of tobacco and alcohol. The ataxic neuropathy resembles that produced by lathyrism (section Proteins, Peptides, and Lectins). A unifying hypothesis about the etiology of these two similar diseases from seemingly very different sources is that thiocyanate accumulation may lead to degeneration of the α -amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA)-containing neurons that are first stimulated and then destroyed in neurolathyrism.¹⁴¹

Similarly, seeds of cycads contain cycasin and neocycasin, which belong to the family of cyanogenic glycosides, as well as neurotoxins. The cyanogenic glycosides of cycads are considered pseudocyanogenic, with little potential to liberate hydrogen cyanide, but most typically produce violent vomiting 30 minutes to 7 hours after ingestion of 1 to 30 seeds.²⁶ On the island of Guam, indigenous peoples develop a devastating amyotrophic lateral sclerosis-parkinsonism dementia complex (ALS-PDC) that appears associated with ingestion of *Cycas circinalis* seeds or the flying foxes that feed extensively upon the cycads.²⁹ The implicated xenobiotic originally was believed to be an excitatory amino acid, but more recently is identified as a sterol glycoside. Research on the mechanism of this cycad-induced disease is ongoing, with the goal of understanding potential mechanisms of this disease and its links to ALS and Parkinson disease.^{19,28}

Anthraquinone Glycosides: Sennoside and Others. Anthraquinone laxatives are regulated both as nonprescription pharmaceuticals and as dietary supplements. These glycosides, such as sennoside, are metabolized in the bowel to produce derivatives that stimulate colonic motility, probably by inhibiting Na⁺K⁺–adenosine triphosphatase (ATPase) in the intestine, which also promote accumulation of water and electrolytes in the gut lumen, producing fluid and electrolyte shifts that can be life threatening.¹⁴⁴

Other Glycosides: Salicin, Atractyloside, Carboxyatractyloside, Vicine, and Convicine. Salicin is an inactive glycoside until it is hydrolyzed to produce salicylic acid (**Chap. 39**). The glycosidic bond is relatively resistant to stomach acid, and the hydrolysis must be accomplished by gut flora. The ability of individual human flora to produce the necessary enzymes

varies significantly, resulting in variable clinical effects for salicin or plant material that contains salicin. However, sufficient hydrolytic capacity for some transformation of the glycoside into salicylic acid occurs in all individuals.

Atractylis gummifera was a favorite agent for homicide during the reign of the Borgias. Atractyloside, the toxic xenobiotic primarily inhibits oxidative phosphorylation in the liver by inhibiting the ADP/ATP antiporter blocking influx of adenosine diphosphate (ADP) into hepatic mitochondria and outflow of ATP to the rest of the cell (Chap. 12). Death or severe illness as a result of liver failure or hepatorenal disease following ingestion is reported.³² *Callilepis laureola* is a South African medicinal plant that contains atractyloside and carboxyatractyloside and is reported to cause human poisonings. Cocklebur (*Xanthium strumarium*) is an herbaceous plant with worldwide distribution. The seeds contain the glycoside carboxyatractyloside. The toxic mechanism is similar to that for atractyloside, and seed ingestion has resulted in human fatalities. Nine patients presented with acute onset abdominal pain, nausea and vomiting, drowsiness, palpitations, sweating, and dyspnea after cocklebur ingestion. Several patients developed hepatocellular damage, renal compromise and myocardial injury, and three developed convulsions followed by loss of consciousness and death.¹⁵¹

Favism is a potentially fatal disorder brought about by eating fava beans or vetch seeds (*Vicia faba*, *Vicia sativa*, respectively). These seeds contain the pyrimidine glycosides vicine and convicine (divicine is the aglycone of vicine). Consumption of these compounds by individuals with an inborn error of metabolism (glucose-6-phosphate dehydrogenase deficiency) can cause acute hemolytic crisis (Chap. 22).¹³⁵

The effects of the glycosides sinigrin (from *Brassica nigra* seed and *Alliaria officinalis* {horseradish} root) and naringen (a polyphenolic glycoside from the grapefruit *Citrus paradisi*) are discussed in the sections on Plant-Induced Dermatitis and Plant–Xenobiotic Interactions, respectively.

Terpenoids and Resins: Ginkgolides, Kava Lactones, Thujone, Anisatin, Ptaquiloside/Thiaminase, and Gossypol

Ginkgolides in *Ginkgo biloba* inhibits platelet aggregation. Reports of spontaneous bleeding associated with ingestion of *Ginkgo* leaf products as an herbal medicine are perhaps explained by this property.¹²³ Another xenobiotic found only in the seed, 4-methoxypyridoxine (pyridine alkaloid), is associated with seizures.⁷⁵ A mechanism similar to isoniazid-induced seizures is plausible, suggesting treatment with pyridoxine phosphate (Chap. 58) (Antidotes in Depth: A14). The dermal effects of *Ginkgo* are discussed in the section Plant-Induced Dermatitis.

Kava lactones are a family of terpene lactones found in kava (*Piper methysticum*) that cause central and peripheral nervous system effects. Kava has enjoyed a long, ceremonial history among islanders of the South Pacific, and observers visiting Oceania have recorded its acute and chronic effects (both pleasant and unpleasant) over the centuries. Importation of kava to Australia in 1983 was a measure to assist Aborigines with alcohol abuse problems. However, the kava itself became abused, and its subsequent ban has resulted in the growth of a black market for kava. Proposed mechanisms to explain the effects of kava lactones include effects at γ -aminobutyric acid type A (GABAA) and GABAB receptors or local anesthetic effects.¹²⁹ Acute symptoms following ingestion include peripheral numbness, weakness, and sedation. Chronic use leads to kava dermopathy and weight loss. More than 70 cases of hepatotoxicity, several requiring liver transplantation, are associated with both acute and chronic effects of kava extracts on cytochrome oxygenases or other yet-to-be-defined etiologies and prompted regulatory health measures in Europe and North America.¹⁴⁸

Thujone is one of many terpenes associated with seizures. It is found in the wormwood plant (*Artemisia absinthium*), in absinthe (the liquor flavored with *A. absinthium*), and in some strains of tansy (*Tanacetum vulgare*). The α - and β -isomers of thujone are believed to act much like camphor to produce CNS depression and seizures. Invoking the structural similarity of thujone to tetrahydrocannabinol (THC), one of the terpenoids of marijuana, to explain the psychoactive effects is controversial (Chap. 77).⁹⁷

Absinthism is characterized by seizures and hallucinations, permanent cognitive impairment, and personality changes. Acute and chronic absinthism led to a worldwide ban of the alcoholic beverage absinthe, which contained thujone, in the early 1900s.¹¹⁰ Over the past several years, there has been a reexamination of the role of absinthe in the seizure disorders previously attributed to this liquor. Modern analytical procedures have been used to analyze the thujone content of vintage absinthe and modern products made using vintage recipes. Results have largely concluded that thujone content in the liquor was likely to be too low to have produced symptoms.⁷⁸ However, because the essential oil of wormwood is composed almost exclusively of thujone, it, not absinthe, is a potent cause of seizures.¹¹⁰ Wormwood oil for making homemade absinthe is currently available and is responsible for at least two reports of adverse reactions in people seeking its hallucinatory or euphoriant effects.¹⁵⁸

Anisatin is found in *Illicium* spp. This terpenoid produces seizures as a noncompetitive GABA antagonist. The Chinese star anise (*Illicium verum*) is sometimes used in teas and occasionally is confused or contaminated with other species of *Illicium*, particularly Japanese star anise *Illicium anisatum*.⁷¹ These contaminations have resulted in small epidemics of tonic-clonic seizures, particularly, but not exclusively, in infants after use of the tea to treat their infantile colic. Recently, in the United States, a case series of at least 40 individuals who had consumed teas brewed from “star anise” experienced

seizures, motor disturbances, other neurologic effects, and vomiting.⁷¹ These cases include at least 15 infants treated for infantile colic with this home remedy. This trend prompted the FDA to issue an advisory regarding the health risk from remedies sharing the common name “star anise.”

Ptaquilosides are found in the bracken fern (*Pteridium aquilinum*), a plant that is extending its range and density worldwide. In foraging animals, consumption of ptaquilosides results in acute hemorrhage secondary to profound thrombocytopenia, whereas thiaminases that are also found in the bracken fern result in cerebral disease.⁴⁷ Although no acute human poisonings are reported, these xenobiotics are transmitted through cow’s milk and are associated with increased prevalence of gastric and esophageal cancer in areas where fern is endemic and consumed by cows whose milk is not diluted.¹⁶³ Chronic toxicity through spore inhalation also produces pulmonary adenomas in animals. More recently, research defined links between alimentary cancer in humans who previously consumed bracken fern fiddleheads.

Gossypol is a sesquiterpene that is derived from cottonseed oil. It has been used experimentally as a reversible male contraceptive. The mechanism for its spermicidal effect is unclear, but the effects have been attributed to inhibition of plasminogen activation and plasmin activity in acrosomal tissue. These effects are not currently reported to produce systemic bleeding. Gossypol also inhibits 11- β -hydroxysteroid dehydrogenase, as does glycyrrhizin and may result in hypokalemia.¹⁶⁴

Proteins, Peptides, and Lectins: Ricin and Ricinlike, Pokeweed, Mistletoe, Hypoglycin, Lathyrins, and Microcystins

Lectins are glycoproteins that are classified according to their binding affinity for specific carbohydrate ligands, particularly galactosamines, and by the number of protein chains linked by disulfide bonds. Toxalbumins such as ricin and abrin are lectins that are such potent cytotoxins that they are used as biologic weapons (**Chap. 133**). Ricin, extracted from the castor bean (*Ricinus communis*; **Fig. 121–3A**), exerts its cytotoxicity by two separate mechanisms.⁹ The compound is a large molecule that consists of two polypeptide chains bound by disulfide bonds. It must enter the cell to exert its toxic effect. The B chain binds to the terminal galactose of cell surface glycolipids and glycoproteins. The bound toxin then undergoes endocytosis and is transported via endosomes to the Golgi apparatus and the endoplasmic reticulum. There the A chain is translocated to the cytosol, where it stops protein synthesis by inhibiting the 28S subunit of the 60S ribosome. In addition to the GI manifestations of vomiting, diarrhea, and dehydration, ricin can cause cardiac, hematologic, hepatic, and renal toxicity. All contribute to death in humans and animals.⁹ Despite the obvious toxicity of this compound, death probably can be prevented by early and aggressive fluid and electrolyte replacement after oral ingestion (but not injection or inhalation; **Chap. 133**). Allergic reactions to some of these lectin-bearing plants and their derivatives are noted.

Just how lethal are ingestions of the ornamental seeds? The highest concentration of xenobiotic is in the hard, brown-mottled seeds. These seeds are both tempting and available, even to children in the United States, because they are attractive enough to be used to make jewelry, and their parent plants are showy enough to have been exported for horticultural purposes outside of their native India (including to the United States). Although mastication of one seed by a child liberates enough ricin to produce death, this outcome (or even serious toxicity) is uncommon, even if the seeds are chewed, probably because GI absorption of the xenobiotic is poor and supportive care is effective.⁵ Activated charcoal should be administered promptly following ingestion.

Other ricinlike lectins are found in *Abrus precatorius* (jequirity pea, rosary pea; **Fig. 121–3B**),³⁸ *Jatropha* spp,⁸² *Trichosanthes* spp (eg. *T. kirilowii* or Chinese cucumber), *Robinia pseudoacacia* (black locust),⁷⁰ *Phoradendron* spp (American mistletoe), *Viscum album* (European mistletoe), and *Wisteria* spp (wisteria). These all produce at least one double-chain lectin that binds to galactose-containing structures in the gut or inhibits protein synthesis in a manner similar to ricin.

FIGURE 121–3. Protein, peptide, and lectin containing plants: (A) The castor bean plant. The seedpods come in bunches, two of which appear near the center of the image. Each seedpod typically contains three seeds. Inset: Castor beans (*Ricinus*

communus) which contain the toxalbumin ricin. By interfering with protein synthesis, ricin may cause multiorgan system failure when administered parenterally. However, its oral absorption is poor, and most oral poisonings cause gastroenteritis. **(B)** Rosary pea (*Abrus precatorius*) containing abrin, a toxalbumin that inhibits protein synthesis. The peas are shown strung together as a rosary. **(C)** Pokeweed (*Phytolacca americana*) has a large rootstock. The unripe berries contain phytolaccatoxin that produces gastroenteritis, but the mature, purple berries are often consumed without toxicity. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

The most commonly ingested toxic plant lectins in the United States are from pokeweed (*Phytolacca americana*; [Fig. 121–3C](#)), which is eaten as a vegetable but rarely causes toxicity or death. The mature, deep purple berries are less toxic. Pokeweed leaves are consumed after boiling without toxic effect if the water is changed between the first and second boiling (parboiling). When this detoxification technique is not followed, as in preparation of poke salad or pokeroor tea, violent GI effects can ensue 0.5 to 6 hours after ingestion. Nausea, vomiting, abdominal cramping, diarrhea, hemorrhagic gastritis, and death may occur. In addition, bradycardia and hypotension, perhaps induced by an increase in vagal tone, may be associated with nausea and vomiting.^{65,121} Phytolaccatoxin and pokeweed mitogen are found in all plant parts, but the highest concentrations are found in the plant root. Pokeweed mitogen is a single-chain protein that inhibits ribosomal RNA by removing purine groups.¹⁴ It produces a lymphocytosis 2 to 4 days after ingestion that may last for 10 days, but is without clinical consequence.

Mistletoe berries, both American and European, can produce severe gastroenteritis, especially when delivered as teas or extracts, or particularly as parenteral antineoplastic medicinal agents in Europe. As festive holiday plants they become seasonally available for children. Poison center data suggest that ingestion of three to five berries or one to five leaves of the American species may not cause toxicity, but these suggestions are based on limited evidence ([Chap. 136](#)). Despite single reports of seizure, ataxia, hepatotoxicity, and death, most authors performing such retrospective examinations conclude that mistletoe exposures are not a highly consequential risk.¹⁴²

Hypoglycin A (β -methylene cyclopropyl-L- α -aminopropionic acid) and hypoglycin B (dipeptide of hypoglycin A and glutamic acid) are found in the unripe ackee fruit and seeds of *Blighia sapida* (Euphorbiaceae). The tree is native to Africa but was imported to Jamaica in 1778 and subsequently naturalized in Central America, southern California, and Florida. The scientific name of the plant derives from Captain William Bligh, the British explorer. Epidemics of illness (Jamaican vomiting sickness) associated with consumption of the unripe ackee fruit (raw and cooked) occur in Africa but are more common in Jamaica, where ackee is the national dish.⁷⁴ The most toxic part is the yellow oily aril of the fruit,²⁷ which contains three large, shiny black seeds. Cases may also be associated with canned fruit.⁹⁶ Hypoglycin A is metabolized to methylene cyclopropyl acetic acid, which competitively inhibits the carnitine–acyl coenzyme (CoA) transferase system.¹¹ This prevents importation of long-chain fatty acids into the mitochondria, preventing their β -oxidation to precursors of gluconeogenesis. β -Oxidation and gluconeogenesis are further arrested by inhibition of various enzymes, such as glutaryl CoA dehydrogenase, which blocks the malate shunt ([Chap. 13](#)). In addition, increased concentrations of glutaric acid may inhibit glutamic acid decarboxylase, which produces GABA from glutamic acid. This not only depletes GABA but also increases concentrations of excitatory glutamate to produce seizures. Insulin concentrations remain unaffected by hypoglycin and metabolites. Carboxylic and other organic acid substrates build up in the urine and serum as a result of these metabolic disturbances. Detection of these acids can help corroborate the diagnosis.¹¹ Jamaican vomiting sickness is characterized by epigastric discomfort and the onset of vomiting starting 2 to 6 hours after ingestion. Convulsions, coma, and death can ensue, with death occurring approximately 12 hours following consumption. Laboratory findings are notable for profound hepatic aminotransferase and bilirubin abnormalities, and aciduria and acidemia without ketonemia. Cholestatic hepatitis can occur and is reported with chronic use.⁸⁰ Autopsy reveals fatty degeneration of liver, particularly microvesicular steatosis, and other organs with depletion of glycogen stores. Left untreated, patient mortality reaches 80%, with 85% of the fatal cases suffering seizures. Treatment with dextrose and fluid replacement is essential. Benzodiazepines can control seizures, but may fail if the seizures are related to depletion of GABA. L-Carnitine therapy may exert a theoretical therapeutic role similar to that noted with valproic acid toxicity ([Chap. 48](#)) (Antidotes in Depth: A8).⁸⁵

The lathyrins β -N-oxalylamino-L-alanine (BOAA) and β -aminopropionitrile (BAPN) are peptides from the grass pea (*Lathyrus sativus*) found in the seeds and leaves, respectively. BOAA produces neurolathyrism and BAPN produces osteolathyrism in individuals with a dietary dependence on this plant. Neurolathyrism is nearly indistinguishable from spastic paresis associated with consumption of improperly prepared cassava (section Cyanogenic Glycosides).^{13,30} Thiol oxidation with depletion of nicotinamide adenine dinucleotide (NADH) dehydrogenase at the level of neuronal mitochondria (ie, excitatory AMPA receptors) may be the common etiology.¹⁴¹ Epidemics have occurred in Bangladesh, Ethiopia, Israel, and India. Exposure to BOAA results in degeneration of corresponding corticospinal pathways that becomes irreversible if consumption of undetoxified grass peas is not stopped early. BOAA stimulates the AMPA class of glutamate receptors to provide constant neuronal stimulation, eventual degeneration, and hence spasticity.¹⁶² BAPN affects bone matrix and leads to bone pain and skeletal deformities that develop in adulthood. These diseases occur in areas where the plants are endemic, the food is consumed for 2 months or more, and when diets are otherwise poor in protein and possibly in zinc.⁵⁷

Microcystins are found in several cyanobacteria (blue-green algae) belonging to various species of the genera *Microcystis*, *Anabaena*, *Nodularia*, *Nostoc*, and *Oscillatoria*. They elaborate a series of peptides called microcystins and nodularins (*Nodularia spumigena*).³⁹ These compounds produce hepatotoxicity by inhibiting phosphatases and causing deterioration of the microfilament function in hepatocytes, leading to cell shrinkage and bleeding into the hepatic sinusoids. Evidence indicates that these peptides are carcinogenic to humans. Although most cases of untoward effects from blue-green algae occur in animals, the potential for harm was demonstrated by use of microcystin-contaminated water in a dialysis unit in Brazil.⁷³ Unfiltered water was identified as the risk factor for liver disease in 100 patients who attended the dialysis center (Chap. 10). Fifty of these patients died of acute liver failure following early signs of nausea, vomiting, and visual disturbances. Of concern, certain species of cyanobacteria are harvested and consumed as health foods or may be consumed secondarily in fish.⁵⁸

Phenols and Phenylpropanoids: Coumarins, Capsaicin, Karwinskia Toxins, Naringenin and Bergamottin, Asarin, Nordihydroguaiaretic Acid, Podophyllin, Psoralen, and Esculose

Phenols and phenylpropanoids represent one of the largest groups of plant secondary metabolites. Coumarins and their isomers are phenylpropanoids that are discussed in Chap. 60. Some coumarins are warfarinlike in their activity and are capable of producing a bleeding diathesis when plants containing them are consumed in sufficiently large quantities.⁶⁸ Lignans are formed when phenylpropanoid side chains react to form bisphenylpropanoid derivatives. Lignins are high-molecular-weight polymers of phenylpropanoids that bind to cellulose and provide strength to cell walls of stem and bark. Tannins are polymers that bind to proteins and divide into two groups: hydrolyzable and condensed forms.

Capsaicin is derived from *Capsicum annuum* or other species of chile or cayenne peppers. Capsaicin is a simple phenylpropanoid that causes release of the neuropeptide substance P from sensory C-type nerve fibers that act upon transient receptor potential (TRP) channels in diverse human tissues.¹⁵⁴ The immediate response to capsaicin is intense local pain and is the rationale for its use as “pepper spray.” Eventual depletion of substance P prevents local transmission of pain impulses from these receptors to the spinal cord, blocking perception of pain by the brain, explaining its use in postherpetic neuralgia.

Painful exposures to capsaicin-containing peppers are among the most common plant-related exposures presented to poison centers. They cause burning or stinging pain to the skin. If ingested in large amounts by adults or small amounts by children, they can produce nausea, vomiting, abdominal pain, and burning diarrhea. Eye exposures produce intense tearing, pain, conjunctivitis, and blepharospasm. Fatality is rare, but has occurred after inhalation and infusion.¹⁴⁰

Skin irrigation, dermal aloe gel, analgesics, and oral antacids are therapeutic agents that may be helpful as appropriate, but patients can be reassured that the effects are transitory and produce no long-term damage. Irritated eyes can be treated with irrigation and local analgesia, but generally resolve without sequelae within 24 hours.

Karwinskia toxins are found in plants commonly named buckthorn, coyotillo, tullidora, wild cherry, or capulincillo (*Karwinskia humboldtiana*). These xenobiotics are identified by their molecular weights (T-514, T-496, T-516, T-544). Toxicity has been known for more than 200 years. In 1920, an epidemic of deaths was reported after 20% of 106 Mexican soldiers died following ingestion of foraged *Karwinskia* fruits.⁹² The fruits are attractive to children. Epidemic poisonings have been reported in Central America and are possible wherever the shrub is found (in semidesert areas throughout the southwestern United States and in the Caribbean, Mexico, and Central America).⁸ Uncoupling of oxidative phosphorylation or dysfunction of peroxisome assembly and integrity is described as the mechanism of action of T-514 on Schwann cells. Each xenobiotic exhibits similar cytotoxic effects at the cellular level, but with tropism for different organs in animal models.⁹²

Within a few days of ingestion, a symmetric motor neuropathy ascends from the lower extremities to produce a bulbar paralysis that may lead to death. Deep-tendon reflexes are abolished in affected areas, but cranial nerve findings are absent. Distinction of this demyelinating motor neuropathy from Guillain-Barré syndrome, poliomyelitis, solvent, and other polyneuropathies is difficult without a history of the fruit ingestion,¹⁰⁸ but can be assisted by detection of T-514 in the blood of affected patients. The other recognized toxins are not detected in blood. Occasionally, axonal damage is observed, but demyelination is the predominant finding on biopsy. Nerve conduction studies always demonstrate loss or abolition of function in fast-conducting axons. Cerebrospinal fluid demonstrates normal protein, glucose, and cytology. Treatment is supportive, with mechanical ventilation as needed, and recovery typically is slow.

Naringin and naringenin are flavonoid, while bergamottin and 6',7'-dihydroxybergamottin are furanocoumarin phenylpropanoids derived from grapefruit that inhibit CYP3A4 in gut and liver. Grapefruit juice consumption can increase circulating concentrations of drugs reliant on CYP3A4 for metabolic elimination, including carbamazepine, felodipine, and the statins. The most plausible mechanism is inhibition of enteric CYP3A4 and P-glycoprotein.¹¹¹ These effects are maximally achieved by a single glass of grapefruit juice.⁸⁹

Comedication with St. John's wort resulted in decreased plasma concentrations of a number of xenobiotics.⁹⁰ Hyperforin is a phenylpropanoid found in St. John's wort (*Hypericum perforatum*) and is associated with plant–xenobiotic interactions through strong induction of CYP3A4 mediated drug metabolism as well as induction of P-glycoprotein. These combined mechanisms can cause subtherapeutic concentrations of xenobiotics metabolized via these pathways.

Asarin is a term sometimes used for the naturally occurring mixture of α - and β -asarones found in the root of *Asarum europaeum*, *Asarum arifolium*, and *Acorus calamus* (sweet flag). Essential oils of the plants have anthelmintic and nematocidal activity, but putative euphoric and hallucinogenic effects that motivate recreational ingestion are in contrast to confirmed reports of unpleasant GI effects.¹⁵²

Nordihydroguaiaretic acid (NDGA) is associated with hepatotoxicity after ingestion of chaparral (*Larrea tridentata*).⁶⁰ Podophyllin and psoralens are phenylpropanoids discussed in the sections Antimitotic Alkaloids and Resins, and Plant-Induced Dermatitis, respectively.

Esculose (also called esculin or aesculin) has triterpene saponin side chains and is believed to be the toxic component in horse chestnut (*Aesculus hippocastanum*). Horse chestnut extracts are used medicinally in patients with venous insufficiency. The therapeutic use of these extracts at high doses ($> 340 \mu\text{g/kg}$) is associated with renal failure or a lupuslike syndrome.⁶¹ Leaves, twigs, or horse chestnuts ingested by children or consumed as a tea by adults results in a syndrome that resembles nicotine intoxication. The syndrome consists of vomiting, diarrhea, muscle twitching, weakness, lack of coordination, dilated pupils, paralysis, and stupor. The mechanism of toxicity is not defined, but massive ingestion of horse chestnuts is suggested to be poisonous to a child.

Carboxylic Acids: Aristolochic Acids, Oxalic Acid, and Oxalate Raphides

Nitrophenanthrene carboxylic acids, collectively called aristolochic acids, are present in most members of the genus *Aristolochia*, including those used ornamentally and as traditional medicines. Consumption of these compounds can cause aristolochic acid nephropathy (AAN), a progressive renal interstitial fibrosis frequently associated with urothelial malignancies (Chap. 45).³⁷ Sources of exposure are via consumption of flour made from wheat contaminated with the seeds of *Aristolochia clematis* or other *Aristolochia* species (so called Balkan endemic nephropathy),⁶² or through use of certain traditional Asian medicines made from *Aristolochia* spp (Chinese herb nephropathy).³⁴

Oxalic acid is the strongest acid among the carboxylic acids found in living organisms. It forms poorly soluble chelates with calcium and other divalent cations. Higher plants have varying ability to accumulate these include both soluble and insoluble oxalates, and many contain crystals of calcium oxalate called raphides. Certain plant families, such as the Araceae, Chenopodiaceae, Polygonaceae, Amaranthaceae, and several of the grass families, are rich in oxalates. Human dietary sources include rhubarb, spinach, strawberries, chocolate, tea, and nuts. Human consumption of soluble oxalate-rich foods correlates with kidney stone formation.⁸⁴

The insoluble calcium oxalate raphides that are present in certain plants, usually in the Araceae family, are found in conjunction with a protein toxin that increases the painful irritation to skin or mucous membranes. This special manifestation is discussed in greater detail in the section Plant-Induced Dermatitis.

Alcohols: Cicutoxin

Cicutoxin, a diacetylenic diol, is found in *Cicuta maculata* (water hemlock), *Cicuta douglasii* (western water hemlock), and *Oenanthe crocata* (hemlock water dropwort). *O. crocata* is native to Europe where intoxications are reported and is now naturalized to the United States. Ingestion of any part of these plants constitutes the most common form of lethal plant ingestion in the United States. Hemlock has dominated plant-related fatalities among the most recent 10-year reviews of the AAPCC data and Centers for Disease Control and Prevention (CDC) plant-poisoning records (Chap. 135). In contrast to most plant exposures in humans, which tend to involve children, these ingestions usually involve adults who incorrectly identify the plant as wild parsnip, turnip, parsley, or ginseng.¹³⁴ All plant parts are poisonous at all times, but the tuber is especially toxic, and more so during the winter and early spring. Absorption of cicutoxin is rapid and occurs through the skin as well as through the gut. Although the mechanism is not fully understood, cicutoxin may noncompetitively inhibit GABA-chloride channels or block potassium channels.¹³⁴

Symptoms of mild or early poisonings consist of GI symptoms (nausea, vomiting, epigastric discomfort) and begin as early as 15 minutes after ingestion. Diaphoresis, flushing, dizziness, excessive salivation, bradycardia, hypotension, bronchial secretions with respiratory distress, and cyanosis occur and rapidly progress to violent seizures. Ingestion of as little as a 2-cm section of the sweet-tasting root of *Cicuta* can produce status epilepticus.¹³⁴ Other complications include rhabdomyolysis with renal failure and severe acidemia. Immediate gastric evacuation should be performed if practical, and benzodiazepines should be administered for seizures. No specific antidote exists; supportive and symptomatic care should be provided.

Unidentified Toxins

Consistent with the inherent complexity of plants and the relatively early stage of the science, identification of the active ingredient(s) involved in poisoning is not always possible. An epidemic of the irreversible lung disease bronchiolitis obliterans developed in Taiwan in 1994 that involved more than 200 dieters who had been eating *Sauropus androgynus* as a weight-loss vegetable. The effects were dose related (usually approximately 100 g/d) and manifested by month 7 after approximately 10 weeks of use.⁶⁹ The cases were associated with at least four deaths, in addition to pulmonary disease resulting in lung transplantation.⁸⁸ Torsade de pointes occurred in three patients, consistent with the plant's high concentration of papaverine, a toxin that produces dysrhythmias in animals. Corticosteroid and bronchodilator therapy consistently failed to improve pulmonary symptoms. A report of a later outbreak in Japan noted that the plant was consumed in an uncooked state.¹⁰⁹

Milk sickness is a historic poisoning described by pioneer farmers. It was caused by transmission of the nontoxic ketone tremetone to humans via milk of animals grazing on white snake-root plants (*Ageratina altissima*, formerly *Eupatorium rugosum*). Tremetone is transformed into an unknown, unstable toxin by hepatic microsomal enzymes.⁸¹ Toxicity is cumulative. Milk sickness can be fatal in 1 to 21 days or is associated with a slow recovery marked by weakness for months or years, relapsing sometimes to death. A delay in the development of the lactating animal's symptoms provided a lag time when xenobiotic-laden milk was taken from asymptomatic animals and thereby transmitted to humans before the problem was detected.

Breynia officinalis, the air potato or bitter yam (*Dioscorea bulbifera*) are associated with hepatotoxicity.⁸⁷ Black cohosh (*Actaea racemosa*) hepatotoxicity is suggested in case reports, but causality is not established.¹⁴⁷

Consumption of the food star fruit (*Averrhoa carambola*) and preexisting renal insufficiency are associated with development of intractable hiccups, vomiting, motor disabilities, paresthesias, confusion, seizures, and death unless patients receive supportive care and hemodialysis.¹⁴⁹ The unidentified toxin appears to be neuroexcitatory and may be oxalate.^{21,49} Charcoal hemoperfusion is reported to be successful but clearance was not determined and causality not confirmed.²⁴

EFFECTS SHARED AMONG DIFFERENT CLASSES OF XENOBIOTICS

Plant–Xenobiotic Interactions

By increasing the metabolic rate of CYP enzymes and P-glycoprotein, hyperforin in St. John's wort (*H. perforatum*) decreases concentrations of several drugs including amitriptyline, cyclosporine, digoxin, indinavir, irinotecan, warfarin, phenprocoumon, alprazolam, dextrometorphan, simvastatin, theophylline, and oral contraceptives.¹¹⁴ Bergamottins and naringenin from grapefruit reduce activity of the CYP system enzymes and increase drug concentrations. Other Citrus species also appear to increase drug concentrations.⁶⁷

Pharmacodynamic interactions may be responsible for serotonin excess or mild serotonin syndrome when St. John's wort is used concurrently with tryptophan or serotonin reuptake inhibitors.¹³² Additive effects also appear to be responsible for increased prothrombin time in patients taking *G. biloba* and various drugs that affect coagulation (eg, warfarin or aspirin) because the ginkgolides have antiplatelet activity.³⁵ Hawthorn (*Crataegus* spp), used medicinally for cardiac disorders, may produce an additive effect when taken concomitantly with digoxin, producing bradycardia. Excessive intake of broccoli provides enough vitamin K to competitively inhibit the effects of warfarin on vitamin K activation.

Sodium Channel Effects: Aconitine, Veratridine, Zygacine, Taxine, and Grayanotoxins

Several unrelated plants produce xenobiotics that affect the flow of sodium at the sodium channel. For instance, aconitine and veratrum alkaloids tend to open the channels to influx of sodium, whereas others (eg, taxine) tend to block the flow, and grayanotoxins both increase and block sodium flow.¹⁵⁵ The sodium channel opener aconitine from *Aconitum* spp or *Delphinium* spp has the most persistent toxicity and the lowest therapeutic index among the many active alkaloid ingredients of these toxic plants called aconite. Some of the related alkaloids are controlled medicinal substances in the People's Republic of China and Taiwan.²⁵ Aconite has been abused for its psychoactive "out of body" effects and for suicide and homicide. These alkaloids should be suspected in potentially poisoned patients who manifest cardiac toxicity, paresthesias, and seizures.

The mechanism of action depends on the individual alkaloid. Some compounds block and others activate sodium channels. Aconitine itself opens the voltage-dependent sodium channel at binding site 2 of the α -subunit, initially increasing cellular excitability.⁵⁵ By prolonging sodium current influx, neuronal and cardiac repolarization eventually slows. It also has calcium channel-opening effects. Those alkaloids are used in Asian prescription medicines to treat dysrhythmias and pain by reducing the excitability of the cardiac conducting system and sensory neurons, respectively.²⁵

Approximately one teaspoon (2–5 mg) of the root may cause death. The aconitine alkaloids are rapidly absorbed from the GI tract, and the calculated half-life of aconitine is 3 hours.¹⁰² CNS symptoms typically progress from paresthesias to CNS depression, respiratory muscle depression, paralysis, and seizures. Nausea, vomiting, diarrhea, and abdominal cramping occur.⁸⁶ Cardiotoxicity resembles that caused by cardioactive steroidal glycosides, and typically progresses from bradycardia with atrioventricular conduction blockade to increased ventricular automaticity resulting in diverse tachydysrhythmias. Multifocal premature ventricular contractions, bidirectional ventricular tachycardia,¹³⁹ torsade de pointes, and ventricular fibrillation may occur.⁸⁶

A history of paresthesias or muscle weakness may be useful in differentiating aconitine toxicity from that caused by cardioactive steroids. Aconite poisoning can be diagnosed by detection of the alkaloids in urine by liquid chromatography-mass spectrometry.

Management should not be delayed while awaiting testing. Empiric use of digoxin-specific antibody fragments should be administered if cardioactive steroid poisoning is strongly considered, but these antibodies are ineffective for aconitine poisoning. Antidysrhythmic success with lidocaine is limited, and amiodarone is currently the antidysrhythmic of choice.⁸⁶ Orogastric lavage, activated charcoal, and preparation for cardiac pacing, bypass, or balloon pump assist should be used as indicated, given the potential for rapid cardiovascular deterioration.

Ingestion of veratridine and other veratrum alkaloids (from *Veratrum viride* and other *Veratrum* spp) generally results from foraging errors where the root appears similar to leeks (*Allium porrum*) and above-ground parts appear similar to gentian (*Gentiana lutea*) used for teas and wines in Europe.¹³³ Typical symptoms develop within an hour of ingestion and include headache followed by nausea, vomiting, and less frequently bradycardia and diarrhea. The mechanism of action is similar to that of aconitine (sodium channel opening) but the duration of effects is shorter.¹⁵⁵ Although severe toxicity has been reported, management is supportive with fluids, atropine, and vasopressors. Deaths are rare.

Zygacine from *Zigadenus* spp (death camas) and other members of the lily family produces the same toxic effects as veratridine alkaloids (vomiting, hypotension, and bradycardia).¹⁵⁹ Symptoms begin 1 to 2 hours after ingestion and usually result from errors while foraging for onions because of the plant's look-alike bulb.¹⁰¹ Treatment options are the same as above with veratrum alkaloids.

Taxine, derived from the yew, is another alkaloid mixture of sodium channel effectors that tend to close the channel (*Taxus baccata*) (Fig. 121–4). The toxicity of *Taxus* has been known since antiquity. Toxic alkaloids are contained within the bark, leaves, and hard central seed but not in the surrounding fleshy red aril, which partly explains the low rate of toxicity in reported cases of unintentional exposure.¹⁶¹ Taxine-derived alkaloids (eg, taxine A and B, isotaxine B, paclitaxel), taxane-derived substances (eg, taxol A and B), and glycosides (eg, taxicatine) are responsible for the toxicity of *Taxus* spp. Lethal oral doses (LD_{min}) of yew leaves in humans are estimated to be 0.6 to 1.3 g/kg of body weight, or 3.0 to 6.5 mg taxines/kg of body weight.^{160,161} Suicide using leaves is reported despite the large number of leaves required.¹⁵⁷ Clinical manifestations of yew poisoning include dizziness, nausea, vomiting, diffuse abdominal pain, tachycardia (initially), and convulsions followed by bradycardia, respiratory paralysis, and death.

FIGURE 121–4. The yew (*Taxus* spp) is a common garden shrub that produces taxine, a cardiotoxin. Though the fleshy red aril is nontoxic, the hard seed it contains is toxic. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Paclitaxel (Taxol) is an alkaloid component of the relatively rare Pacific yew (*Taxus brevifolia*) that is used as an

antitumor chemotherapeutic xenobiotic because of its ability to promote the assembly of microtubules and to inhibit the tubulin disassembly process in mitotic cells. Within one hour after ingestion, toxicity progresses from nausea, abdominal pain, bradycardia, and cardiac conduction delays to wide-complex ventricular dysrhythmias, paresthesias, ataxia, and mental status changes. Four prisoners who drank an extract of yew experienced profound hypokalemia, and two died of cardiac arrest.⁵¹ Animal models indicate that bradycardia is responsive to atropine, but wide-complex tachydysrhythmias are unresponsive to sodium bicarbonate.¹²⁴

Grayanotoxins (formerly termed andromedotoxins) are a series of 18 toxic diterpenoids present in leaves of various species of *Rhododendron*, *Azalea*, *Kalmia* (Fig. 121–5), and *Leucothoe* (Ericaceae). They exert their toxic effects via sodium channels, which they open or close, depending on the toxin.¹⁵⁵ Grayanotoxin I increases membrane permeability to sodium and affected calcium channels in a manner similar to that of veratridine (and batrachotoxin).⁷² Grayanotoxins can become concentrated in honey made in areas with densely populated grayanotoxin-containing plants, mainly in the Mediterranean. Accounts of poisoning by honey date back to at least 401 bc when Xenophon's troops were incapacitated after they consumed honey made from nectar of *Rhododendron luteum*. Occasionally, grayanotoxin-containing plants or plant preparations rather than honey cause human poisonings. Bradycardia, hypotension, GI manifestations, mental status changes ("mad honey"), and seizures are described in patients or animals suffering grayanotoxin toxicity.⁶³

FIGURE 121–5. Mountain laurel (*Kalmia latifolia*), an evergreen shrub, contains the sodium channel opener grayanotoxin, which produces dysrhythmias. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Antimitotic Alkaloids and Resins: Colchicine, Vincristine, and Podophyllum

Consumption of colchicine from plant sources such as autumn crocus (*Colchicum autumnale*) produces a spectrum of effects, including nausea, vomiting, watery diarrhea, hypotension, bradycardia, electrocardiographic abnormalities, diaphoresis, alopecia, bone marrow depression, renal failure, hepatic necrosis, acute respiratory distress syndrome, convulsions, and death.¹⁴⁶

Confusion of the bulbs or leaves of this plant with those of wild onions or garlic occur as a foraging error. Unintentional consumption by children and ingestion with suicidal intent account for the other cases involving morbidity or mortality. The mechanism of toxicity is the disruption of microtubule formation in mitotic cells.⁵³

Vincristine and vinblastine are two other indole alkaloids that are used as antineoplastics and are both isolated from the Madagascar periwinkle (*Catharanthus roseus*). No reports of poisoning by these alkaloids following ingestion of the plant could be found (Chap. 37).

Podophyllum resin is the dry, alcoholic extract of the rhizomes and roots of mayapple (*Podophyllum peltatum*) (Fig. 121–6). The dry resin consists of up to 20% podophyllotoxin, α - and β -peltatin, desoxypodophyllotoxin, and dehydropodophyllotoxin. These xenobiotics are originally present in the plant as β -D-glucosides. Podophyllum resin containing podophyllin is available by prescription for topical treatment of venereal warts. Its medicinal derivative, etoposide, is used for a range of neoplastic diseases. Podophyllum is used as a popular traditional Chinese medicine. Podophyllotoxins make up 20% of the resin from the roots of mayapple (*P. peltatum*). As a group, they disrupt tubulin formation, producing multisystem organ failure. Poisonings are caused by misidentification and adulteration, possibly because the list of common names by which it is known includes mayapple, as well as mandrake, wild mandrake, American mandrake, and European mandrake.⁵⁴ Catharsis is prominent after ingestion, but onset of symptoms may be significantly

delayed. Acute, severe sensorimotor neuropathy and bone marrow suppression following transient leukocytosis can occur even after acute exposures and may be directly related to inhibition of microtubule assembly. Lethargy, confusion, encephalopathy, autonomic instability, sensory ataxia, and death are described following large exposures,¹⁰⁷ but poisoning has also occurred after “therapeutic” doses of a popular traditional Chinese medicine.¹¹⁴

FIGURE 121–6. The mayapple (*Podophyllum peltatum*) develops from an initial nodding flower that grows from the stem of this low lying ground cover plant. The whole plant contains podophyllotoxin (podophylline), though the apple is generally considered the least toxic part. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Glutamic acid has been used to prevent vincristine-induced peripheral neuropathy and would be a reasonable therapy following podophyllin ingestion.¹⁰¹

Plant-Induced Dermatitis

A large number of plants result in undesirable dermal, mucous membrane, and ocular effects, and they represent the most common adverse effects reported to US poison centers and occupational health centers. Plant-induced dermal disorders can be readily categorized into four mechanistic groups, that is, dermatitis that results from (1) mechanical injury, (2) irritant molecules that penetrate the skin, (3) allergy, or (4) photosensitivity (direct and hepatogenous) (Chap. 18).¹³⁰

There is much overlap between these categories (some plants can produce all types). Clinicians may have difficulty distinguishing between plant-induced dermatitis and skin disorders⁹⁴ or between plant-induced dermatitis and pseudophytophysitis caused by arthropods, pesticides, or wax (used in fruit and vegetable packaging). Agents that cause adverse skin reactions can also cause eye and local gastric mucosal irritation.

Dermatitis from mechanical injury often is combined with primary or allergic contact dermatitis. Stinging nettles (*Urtica dioica* and other species) have a specialized apparatus in the form of an elongated silicious cell (glandular trichome) that acts like a hypodermic syringe to deliver irritant chemicals into the skin. Contact with these stinging hairs shears off the tip of the hair, producing micromechanical injury and releasing irritant contents: acetylcholine, histamine, and 5-hydroxytryptamine.⁴ Acute motor polyneuropathy associated with cutaneous exposure to *Urtica ferox* is reported within 48 hours of walking through a patch of the nettles, with recovery occurring over several weeks.⁶⁶ The barbed trichomes (spicules) of *Mucuna pruriens* (velvet bean, cowhage) evoke a histamine-independent itch that is mediated by a cysteine protease, mucunain.⁷⁹ Workers who handpick pineapples are subject to fissuring and loss of fingerprints after proteolytic enzyme bromelain exposure following dermal abrasion by raphides.

Exposures to commonly available household plants such as dumbcane (*Dieffenbachia* spp), *Philodendron* spp, and *Narcissus* bulbs can lead to mechanical injury and painful microtrauma produced by bundles of tiny needlelike calcium oxalate crystals called raphides.¹⁰⁶ Packages of hundreds of raphides called idioblasts contain proteolytic enzymes. *Dieffenbachia* (more than 30 species) (Fig. 121–7) exposures are commonly reported household or malicious plant exposures, although such exposures are rarely serious.¹⁰⁴ When the leaves are chewed, immediate oropharyngeal pain and swelling occur.³¹ Severe oral exposures can be excruciating and progress to profuse salivation, dysphagia, and loss of speech. Soothing liquids, ice, parenteral opioids, corticosteroids, and airway protection may be indicated, but antihistamines provide little relief. The edema and pain typically begin to subside after 4 to 8 days. Ocular exposure to the sap may produce chemical conjunctivitis, corneal abrasions, and, rarely, permanent corneal opacifications.

FIGURE 121–7. This dumbcane (*Dieffenbachia* spp) plant is representative of the Arum family, which typically have variegated, waxy leaves. Many contain insoluble crystals of calcium oxalate arranged in idioblasts, which may be ejected following trauma to the leaf. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Similar exposures to oxalate raphide-containing household plants in the same family (*Philodendron*, *Brassaia*, *Epipremnum aureum*, *Spathiphyllum*, and *Schefflera* spp) are not as painful as those to dumbcane, presumably because the crystals are packaged differently and do not simultaneously deliver proteolytic enzymes.¹⁰⁶ One exception to their lower severity is a report of death in an 11 month-old child following complications arising from esophageal lesions induced by *philodendron*.⁹⁵

Irritant dermatitis can result from low-molecular-weight xenobiotics such as phorbol esters (from *Euphorbiaceae*) that directly penetrate the skin without antecedent mechanical injury. Similar penetrance is achieved by products of glycoside hydrolysis. For instance, hydrolysis of ranunculin gives rise to anemonin in *Ranunculaceae*, the buttercup family, and hydrolysis of sinigrin in plants in the mustard family *Brassicaceae* yields allyl isothiocyanate. Exposures to primary irritants in *Brassicaceae* and *Ranunculaceae* usually are mild. Alternatively, airborne contact dermatitis occurs in typically exposed sites such as the upper eyelids, neck, uncovered extremities, including antecubital fossae, and other skin folds (Chap. 18).⁹⁹

Phorbol esters found in spurge (*Euphorbiaceae*) are contained in milky sap that is capable of producing erythema, desquamation, and bullae. The saps of some species are more irritating than others. For instance, the manchineel tree (*Hippomane mancinella*), found in the Caribbean and Florida, once was planted on graves to deter grave robbers, and juice from the tree has been used to brand animals and to blind people. In addition to dermal and ocular injury,⁴⁶ ingestion of some spurge can induce severe GI injury. Poinsettia (*Euphorbia pulcherrima*), crown of thorns (*Euphorbia splendens*), candelabra cactus (*Euphorbia lacteal*), and pencil tree (*Euphorbia tirucalli*) are spurge found in the home as holiday or other ornamentation that rarely produce serious injury, despite reputations to the contrary. The poinsettia plant, for instance, gained a reputation of significant toxicity based on a single, inadequately documented case report from Hawaii in 1919, involving the death of a 2 year-old child.⁷ In a subsequent case, an 8 month-old child developed oral mucosal burns after chewing poinsettia.⁴⁵ Contact dermatitis, irritation of mucous membranes, and GI complaints such as nausea, vomiting, and abdominal pain are rare findings among the many reported exposures to poinsettia.

Allergic contact dermatitis results from type IV hypersensitivity response and, unlike irritant dermatitis, requires repeat exposures to the agent before symptoms manifest. The most infamous of these xenobiotics are the urushiol oleoresins derived from catechols that are found in *G. biloba* (*Ginkgoaceae*) and members of the *Proteaceae* (eg, *Macadamia integrifolia*) and the *Anacardaceae*. The latter family is notable for inclusion of poison ivy (*Toxicodendron radicans*),

poison oak (*Toxicodendron toxicarium*, *Toxicodendron diversilobum*), and poison sumac (*Toxicodendron vernix*),⁵⁹ as well as mango (*Mangifera indica*), pistachio (*Pistacia vera*), cashew (*Anacardium occidentale*), and Indian marking nut “Bhilawanol” (*Semecarpus anacardium*). Upon first exposure, urushiol resins penetrate the skin and react with proteins to form antigens to which the body forms antibodies. Upon reexposure to urushiol resins, inflammatory mediators are released, leading to urticaria, itching, swelling, and pain. In extreme cases, these reactions can progress to type I hypersensitivity. Cross-reactivity between allergens is possible, and particular vigilance is required in sensitive individuals.⁵² Prevention by removal of exposed objects that act as fomites for the oils and use of protective linaments are appropriate. Therapy includes washing with soap and water and corticosteroid creams and, for those frequently exposed, desensitization (Chap. 18).⁵⁹

Allergic contact dermatitis is the most common plant-induced occupational injury. In the United States, 33% of 462 floral shops surveyed reported that at least one employee had developed contact dermatitis.¹²⁸ Reactions are reported following exposure to tulips, *Narcissus*, Peruvian lily (*Alstroemeria* spp), and primroses (*Primula* spp). Exposure to the glycoside tuliposide A results in “tulip fingers,” the dry, painfully fissured hyperkeratosis of fingers observed in horticultural workers who chronically handle tulips.²⁰ Upon hydrolysis, this compound yields α -methylene-butylolactone, the true allergen. Cross-reactivity is possible among some of these xenobiotics. *Alstroemeria* spp, a common ornamental called Peruvian lily, contain tuliposide A and thus can cross-react with antigens in those persons already allergic to tulips, producing an allergic contact dermatitis. Primin (2-methoxy-6-n-pentyl-p-benzoquinone) from members of the Primulaceae family was responsible for the most frequently reported allergic plant dermatitis in northern Europe until workers refused to stock primroses. The “wood cutters dermatitis” of loggers occurs with development of sensitivity to compounds in liverwort (*Frullania* spp), which is cross-reactive to usnic acid in lichens and mosses found on the wood. Cross-reactivity with common weeds such as ragweed (*Ambrosia* spp) or dandelion (*Taraxacum* spp) initiate the risk of hypersensitivity from members of the Compositae family.⁷⁶ A myriad of other types of plants are involved in producing occupational dermatitides.^{106,128} Sensitivity to Compositae (daisy family) involves more than 600 sesquiterpene lactones in at least 200 of the 25,000 species in the family and is as ubiquitous as the distribution of species. Chrysanthemum allergy is a common occupational hazard in Europe.

Direct photosensitivity dermatitis is produced when compounds such as psoralens or other linear furocoumarins come into direct contact with the skin or are digested and become bloodborne to dermal capillary beds, where they interact with sunlight. These photosensitizing agents are activated by ultraviolet A radiation (320–400 nm), producing singlet oxygen and DNA adducts. In addition to severe sunburnlike symptoms (erythema, epidermal bullae), hyperpigmentation lasting for several months may result from exposure to these compounds. The mechanism by which this reaction is produced is unknown, but depletion of glutathione is postulated to indirectly stimulate melanogenesis by disinhibiting the normally suppressant tyrosinase.⁹¹ More than 200 of these xenobiotics have been identified in at least 15 plant families, including food sources, such as Apiaceae (anise, caraway, carrot, celery, chervil, dill, fennel, parsley, and parsnip), Rutaceae (grapefruit, lemon, lime, bergamot, and orange), Solanaceae (potato), and Moraceae (figs) family.

Hepatogenous photosensitivity is produced when a xenobiotic that normally is harmlessly ingested, absorbed, and hepatically excreted gains access to the peripheral circulation through failure of a liver excretion or detoxification mechanism. An example is the photosensitivity that occurs when phyloerythrin, a product of chlorophyll digestion normally eliminated in the bile, accumulates in the blood as a result of liver dysfunction. The cyanobacterium *Microcystis aeruginosa*, as well as the plants *Lantana camara*, *Tribulus terrestris*, and *Agave lechuguilla* reportedly cause this type of photosensitization in animals.

SUMMARY

- Plant exposures are among the commonest human exposures but also typically have the least morbidity and mortality.
- Plant xenobiotics can be organized by the principles of pharmacognosy.
- Some xenobiotics act directly or are metabolized to toxic principles such as tremetone, whereas others are toxic through secondary contact in animal meat or milk such as coniine, nitrates, pyrrolizidine alkaloids, and ptaquiloside.
- Some reassurance can be achieved by excluding exposure to the most life-threatening plants.

122 NATIVE (US) VENOMOUS SNAKES AND LIZARDS

Anne-Michelle Ruha and Anthony F. Pizon

HISTORY AND EPIDEMIOLOGY

Snakes

Over 3000 species of snakes have been identified worldwide, with nearly 800 species considered venomous. All venomous species are classified taxonomically into one of four general groups. These include the families Viperidae, Elapidae, and Colubridae, as well as the Atractaspidinae, a subfamily of the Lamprophiidae family.⁴⁹ The United States is home to nearly 30 species and subspecies of venomous snakes (Table 122–1), with many more found throughout Mexico. All belong to the Crotalinae subfamily of Viperidae or to the Elapidae family.

TABLE 122–1. Medically Important Snakes of the United States

Genus	Species	Common Name
Crotalinae		
<i>Crotalus</i>	<i>adamanteus</i>	Eastern Diamondback rattlesnake
	<i>atrox</i>	Western Diamondback rattlesnake
	<i>cerastes</i>	Sidewinder ^a
	<i>cerberus</i>	Arizona Black rattlesnake
	<i>horridus</i>	Timber rattlesnake
	<i>lepidus</i>	Rock rattlesnake ^a
	<i>mitchellii</i>	Speckled rattlesnake ^a
	<i>molossus</i>	Black-tailed rattlesnake ^a
	<i>oreganus</i>	Western rattlesnake ^a
	<i>pricei</i>	Twin-spotted rattlesnake ^a
	<i>ruber</i>	Red diamond rattlesnake ^a
	<i>scutulatus</i>	Mojave rattlesnake ^a
	<i>tigris</i>	Tiger rattlesnake
	<i>viridis</i>	Prairie rattlesnake ^a
	<i>willardi</i>	Ridgenose rattlesnake ^a
<i>Sistrurus</i>	<i>catenatus</i>	Massasauga ^a
	<i>miliarius</i>	Pygmy rattlesnake ^a
<i>Agkistrodon</i>	<i>contortrix</i>	Copperhead ^a
	<i>piscivorus</i>	Cottonmouth ^a
Elapidae		
<i>Micrurus</i>	<i>fulvius</i>	Eastern coral snake
<i>Micrurus</i>	<i>tener</i>	Texas coral snake ^a

^aSubspecies identified for this species.

Venomous snakes possess glands that are associated with specialized teeth, or fangs, which allow delivery of venom for the purpose of prey immobilization or defense. Fangs are located in the front of the mouth in most venomous species. In addition to fangs, venomous snakes have rows of small teeth that may cause additional injury during a bite.

The majority of snake species in North America are rear-fanged, non-venomous members of the Colubridae family. Bites by these species, which include corn snakes, gopher snakes, and garter snakes, are usually harmless. Colubrids do not possess venom glands, but may produce secretions from Duvernoy's glands that contain toxins similar to those found in the venom of venomous species. Although the vast majority of bites by nonvenomous colubrids do not produce symptoms, rare cases of envenomation have been documented following a bite by a nonvenomous species.⁵⁷

Venomous snakes are found throughout most of the United States. They are much more common in the southern and western states than in the northern states. Though venomous species are not endemic to Maine, Alaska, or Hawaii, bites have been reported in every state except for Hawaii. The true number of bites that occur each year is not accurately known, but an average of 5000 native venomous snakebites are reported to US poison centers annually.⁴³ Mortality is rare, with fewer than 10 deaths per year reported. Epidemiologic data on snakebites in Mexico is poor, but the number of bites and deaths is thought to be higher.²⁹

The majority of snakebites occur between April and September, with the peak number reported in July. Men comprise 75% of snakebite victims and children represent about 10% to 15% of reported cases.⁴³ Most victims are bitten on an extremity, although bites to the torso, face, and tongue also occur. Over half of reported bites occur when an individual is purposely handling a known venomous snake. Herpetologists, those who capture and keep wild snakes, and religious snake handlers are at highest risk. Occasionally people are envenomed after killing and decapitating a rattlesnake. This is likely due to persistent reflexes in the venom apparatus.

Snake handlers and collectors are at risk for multiple bites during their lifetime. There is no convincing evidence that immunity develops as a result of repeated envenomation. Victims of repeat bites may actually have a greater risk for anaphylaxis because of prior sensitization and the development of IgE antibodies to venom.

Snake enthusiasts often keep nonnative species as pets. Approximately 30 to 50 bites from a large variety of exotic venomous snakes are reported to poison centers each year.⁴⁵

Pit Vipers. The majority of native venomous snakes are members of the Crotalinae subfamily of Viperidae. These crotaline species are variably referred to as crotalids, new world vipers, or pit vipers. The term 'pit viper' describes the presence of a pitlike depression behind the nostril that contains a heat-sensing organ used to locate prey. Native pit vipers include the rattlesnakes (genera *Crotalus* and *Sistrurus*) and the cottonmouths and copperheads (genus *Agkistrodon*). These pit vipers can be distinguished from native nonvenomous species by a triangular-shaped head, vertically elliptical pupils, and easily identifiable fangs (Fig. 122-1). Crotalinae have front, mobile fangs that are paired, needlelike structures that can retract on a hingelike mechanism into the roof of the mouth. Rattlesnakes have the longest fangs, reaching 3 to 4 cm. Pit vipers may also be identified by their scales. Their undersurface has a single row of plates or scales, as opposed to the double row found on nonvenomous species. Rattlesnakes may or may not have rattles, depending on maturity. A rattling sound is often, but not always, heard before a strike. Copperheads and cottonmouths do not have rattles, but may shake their tails similarly to rattlesnakes. Cottonmouths, which are also commonly known as water moccasins, are semiaquatic and have a distinct white mouth. Copperheads are known for their reddish-brown (copper) heads and hourglass markings on their bodies (Fig. 122-2)

FIGURE 122-1. Pit vipers have a triangular shaped head, vertically elliptical pupils, and heat-sensing pits behind the nostril.

FIGURE 122–2. Copperhead (*Agkistrodon contortrix*).

The vast majority of North American snake envenomations are from bites by crotalids. Of those bites for which the type of snake is reported, about half are rattlesnake species, and the remainder copperheads and cottonmouths. Rattlesnakes are found throughout most of the United States, but encounters are most common in western and southern states. Rattlesnakes account for the greatest morbidity among the various types of pit vipers. Deaths following snakebite are almost always due to rattlesnakes, although rare deaths have been associated with copperhead bites. Copperhead bites are most often reported in the eastern and southeastern United States, although they also occur in the northeast. Cottonmouths are found mainly in the southeastern United States.⁴³

Coral Snakes. Coral snakes (genera *Micrurus* and *Micruroides*) represent the Elapidae family in North America. These brightly colored snakes typically have easily identifiable red, yellow, and black bands along the length of their bodies. In the United States, coral snakes and the similarly colored nonvenomous scarlet king snake are often confused. Coral and king snakes can be distinguished by their color patterns. Whereas coral snakes have black snouts, king snakes have red snouts. Both species have red, yellow, and black rings, but in different sequences: the red and yellow rings touch in the coral snake but are separated by black rings in king snakes (“Red on yellow kills a fellow; red on black, venom lack”) (Fig. 122–3). This general rule for identifying coral snakes does not apply to Mexican species, some of which may have different color patterns

FIGURE 122–3. Coral snake with characteristic black snout and red bands bordered by yellow bands. (Used with permission of Banner Good Samaritan Medical Center Department of Medical Toxicology.)

Elapids possess front fixed fangs. The fangs of coral snakes are small, and discrete fang marks may not be obvious after envenomation. Coral snakes often latch on to a victim or “chew” for a few seconds in an attempt to deliver venom. A history of this activity may help identify a coral snakebite when the offending reptile cannot be located.

Coral snakes are responsible for approximately 2% of bites reported to US poison centers.⁴³ *Micrurus* species are found in 11 southeastern states, where up to 100 bites are reported per year. *Micrurus fulvius* (the Eastern coral snake) is responsible for the greatest morbidity and mortality, while *M. tener* (the Texas coral snake) seems to be less dangerous. The Sonoran coral snake (*Micruroides euryxanthus*) does not produce envenomation necessitating medical intervention.⁵⁶

Lizards. There are two species of lizard that are known to produce envenomation in humans. These are the Gila monster *Heloderma suspectum* (Fig. 122–4), which is native to the desert southwestern United States, and the beaded lizard *H. horridum*, which is found in Mexico. Both species are members of the Helodermatidae family. These lizards are slow moving, nocturnal, and thick bodied. Adults may reach a length of 60 cm and are generally shy, so bites are relatively rare and usually occur as a result of handling. Gila monsters are known for their forceful bites. They can hang on and “chew” for as long as 15 minutes, and they may be difficult to disengage¹⁸

FIGURE 122–4. (A) Young Gila monster (*Heloderma suspectum*). (B) Beaded lizard (*Heloderma horridum*).

The helodermatid lizards have a less effective venom delivery system than venomous snake species. The lizards possess paired venom glands that are located on either side of the anterior lower mandible. Venom ducts carry the venom from the glands to the base of grooved teeth. When a tooth produces a puncture wound, the venom travels by capillary action into the grooves and then into the wound.⁴⁰

Bites by the Gila monster and beaded lizard are extremely uncommon, even in areas where the lizards are endemic. Bites almost always occur from captive animals, whether found in the wild or kept in a zoo or personal collection. The great majority of reported cases have involved adult men.

PHARMACOLOGY

Snakes

Snake venom is a complex mixture of proteins, peptides, lipids, carbohydrates, and metal ions. Venom may contain a variety of enzymes including phospholipases A₂ (PLA₂s), metalloproteinases (SVMPs), serine proteases, acetylcholinesterases, L-amino acid oxidases, and hyaluronidases. Non-enzymatic proteins include three finger toxins (3FTXs), sarafotoxins, disintegrins, and C-type lectins among others. The content and potency of venom in any given snake may vary depending on age, diet, and geography. Thus an adult snake may have significantly different venom composition than a young snake of the same species.⁵⁴

Snakes typically produce about 100 to 200 mg dry venom in a single milking, although some may produce several hundred mg to over 1 g.⁵⁴ Many venom components are pharmacologically active and target receptors, ion channels, enzymes, or other proteins in mammals. The actions of only a fraction of snake venom components are fully understood. Identification of individual snake venom toxins, understanding of pharmacologic mechanisms, and potential medicinal uses for venom are areas of ongoing research.

Lizards. Helodermatid venom contains a complex mixture of components similar to those of snake venoms, including numerous enzymes such as hyaluronidase, phospholipase A₂, and serotonin.^{40,52} Nonenzymatic components include helospectins and helodermin, which are vasoactive peptides that activate adenylyl cyclase, and exendin-3 and exendin-4, which stimulate glucose-dependent insulin secretion. Discovery of exendins in Heloderma venom lead to development of exenatide (Byetta), a glucagon-like peptide-1 (GLP-1) receptor agonist used in the management of diabetes.^{20,52} Another important component of Heloderma venom is gilatoxin. Gilatoxin is a serine protease with kallikreinlike activity, thought to be responsible for the hypotension and angioedema that occur in some human envenomations.⁵²

PHARMACOKINETICS AND TOXICOKINETICS

Snakes

Very few pharmacokinetic studies of snake venom exist, and much remains unknown regarding absorption, distribution, and elimination of venom following a bite. When a snake bites, venom is usually deposited subcutaneously. In some cases fangs may reach muscle or even directly access vasculature. Systemic absorption of venom usually occurs via the lymphatic system. Available human and animal data suggest that venom antigens are absorbed into blood within minutes of envenomation, with peak concentrations detected within 4 hours.^{8,26,44} Venom antigen concentrations measured in the first 4 hours following a bite correlate roughly with grade of envenomation.^{2,7,26} Venom antigens are also detected in urine as early as 30 minutes after envenomation.²⁶ After administration of adequate doses of antivenom, venom antigens are no longer detected in blood; however, antigenemia may recur, and such recurrence is associated with reemergence of clinical effects.^{26,44}

The elimination half-life of snake venom appears to be long. Following subcutaneous injection of C atrox venom in a rabbit model, mean half-life was 20 hours, and venom was still detectable in blood at 96 hours.⁸

Lizards. Pharmacokinetic studies of helodermatid venom are not available. Clinical reports suggest that venom is absorbed systemically within minutes of a bite.

PATHOPHYSIOLOGY

Snakes

Pit Vipers. Crotaline venom can simultaneously damage tissue, affect blood vessels and blood, and alter transmission at the neuromuscular junction. It is difficult to attribute specific pathology or pathophysiology to any particular component of snake venom. In fact, clinical effects often occur as the result of several venom components (Table 122–2). For instance, local tissue damage results from venom metalloproteinases and hyaluronidase, which both contribute to swelling through disruption of the extracellular matrix and basement membrane surrounding microvascular endothelial cells.²⁴ As a result of reduced blood flow through damaged capillaries, they may also contribute to myonecrosis, which results primarily from the action of phospholipase A₂ enzymes (PLA₂) on muscle.²⁴ Additionally, venom metalloproteinases contribute to

dermatonecrosis, both directly and through activation of endogenous inflammatory mediators.^{24,48}

TABLE 122–2. Major Venom Components of Crotalinae Snakes

<i>General Clinical Effect</i>	<i>Responsible Venom Components</i>
Local tissue damage	Metalloproteinases Phospholipases A ₂ Hyaluronidase
Coagulation effects ^a	C-type lectinlike proteins Metalloproteinases ^b Serine proteases ^b Phospholipases A ₂
Platelet effects ^c	Disintegrins C-type lectinlike proteins Metalloproteinases Phospholipases A ₂
Neurotoxic effects	Phospholipases A ₂

^aVenom contains both pro- and anticoagulants, with anticoagulant effects predominating in North American crotaline envenomation. ^bInclude thrombinlike enzymes as well as fibrinogenolytic enzymes. ^cVenom may contain factors that inhibit, activate, or affect aggregation of platelets.

Venom effects on the hematologic system are especially complex. Numerous components act as anticoagulants, and many others act as procoagulants. Similarly, platelets may be inhibited, activated, agglutinated, aggregated, or inhibited from aggregating by various venom components. Venom components can be grouped according to certain characteristics, such as structure and enzymatic activity, but as noted above with local tissue damage, components within several groups may contribute to similar effects. For instance, anticoagulants in snake venoms are found among the C-type lectinlike proteins (CLPs), PLA₂ enzymes, serine proteases, and metalloproteinases. Conversely, components within a single group may have many different actions. Various CLPs in venom act as anticoagulants, procoagulants, or platelet modulators. PLA₂ enzymes are especially diverse, acting as anticoagulants and platelet modulators in addition to producing myotoxic and neurotoxic effects. Platelet effects result mainly from the action of disintegrins, although CLPs, PLA₂ enzymes, and other proteinases also have platelet-modulating effects.^{36,60}

Specific hematologic effects are species dependent, with no single venom containing all of the identified hemostatically active components. Of particular importance to North American rattlesnake envenomation are the thrombinlike enzymes and fibrinogenolytic enzymes. These are metalloproteinases and serine proteases that preferentially cleave fibrinopeptide A or fibrinopeptide B from fibrinogen. Unlike thrombin, they do not activate factor XIII. The end result is production of a poorly cross-linked fibrin clot that easily degrades. Multiple other venom components exist, some of which affect the vascular system and contribute to the hypotension that sometimes occurs clinically. Examples include bradykinin-potentiating peptides and vascular endothelial growth factors.^{47,60}

Snake neurotoxins act at the neuromuscular junction and do not cross the blood–brain barrier. They are classified as α -neurotoxins, which act postsynaptically, and β -neurotoxins, which act presynaptically. The Mojave rattlesnake, *C. scutulatus*, is known for its neurotoxic venom. The neurotoxin, Mojave toxin, is a PLA₂ that acts at the presynaptic terminal of the neuromuscular junction to inhibit acetylcholine release. The presence of Mojave toxin in venom appears to be geographically distributed, with Mojave rattlesnake populations in California and southeast Arizona possessing functional Mojave toxin, and central Arizona populations lacking the neurotoxin.^{22,59} Mojave toxin has also been identified in the venom of the Southern Pacific rattlesnake (*C. oreganus helleri*) found in southern California, and envenomations by this species have produced neurologic symptoms.^{10,19}

Coral Snakes. Coral snake venom contains neurotoxins that produce systemic neurotoxicity. Unlike crotaline venom, coral snake venom does not cause local tissue injury. Similar to neurotoxins present in other elapid species, α -neurotoxins bind and competitively block post synaptic acetylcholine receptors at the neuromuscular junction, leading to weakness and paralysis. Phospholipase A₂ can also cause myotoxicity, although this appears to be of less clinical importance. The LD₅₀ of *M. fulvius* venom is lower than that of *M. tener* venom, which corresponds to the more severe effects noted in humans following Eastern coral snake envenomations.⁴¹

Lizards. The pathophysiology of helodermatid venom is poorly understood. It is suggested that hyaluronidase

contributes to spreading of venom throughout tissue.⁴⁶ Gilatoxin is believed to produce hypotension and other findings such as angioedema by increasing bradykinin levels.⁵²

CLINICAL MANIFESTATIONS

Snakes

The clinical presentation of North American snake envenomation is highly variable and depends upon many factors, including the species of snake, the amount and potency of venom deposited, the location of the bite, and patient factors, such as comorbidities. It is important for the clinician to be familiar with endemic venomous snake species in order to anticipate clinical effects when presented with an envenomed patient. For bites by nonnative species, it is imperative to identify the species so that specific antivenom can be sought.

Pit Vipers. Envenomation by North American pit vipers is characterized by local swelling and cytotoxic effects. Hematologic effects are common, and there is the potential for development of systemic illness and neurotoxicity. Most patients exhibit only a subset of possible effects of envenomation. In addition, some of the signs and symptoms in a given individual, such as nausea or tachycardia, may be related to fear rather than to envenomation.

The clinical presentation following a pit viper bite can range from benign to life threatening (Table 122–3). One finding common to all victims is the presence of an identifiable disruption of skin integrity. Most commonly, one or two distinct punctures are present, though occasionally, patients exhibit multiple punctures, small lacerations, or scratches.

TABLE 122–3. Evaluation and Treatment of Crotaline Envenomation				
Extent of Envenomation	Clinical Observations	Antivenom Recommended ^a	Other Treatment	Disposition
None (“dry bite”)	Fang marks may be seen, but no local or systemic symptoms after 8–12 hours	No	Local wound care Tetanus prophylaxis	Discharge after 8–12 hours of observation
Minimal	Minor, nonprogressing, local swelling and discomfort without systemic symptoms or hematologic abnormalities	No	Local wound care Tetanus prophylaxis	Admit to monitored unit for 24-hour observation
Moderate	Progression of swelling beyond area of bite with or without local tissue destruction, hematologic abnormalities, or non–life-threatening systemic symptoms	Yes	IV fluids Cardiac monitoring Analgesics Follow laboratory parameters Tetanus prophylaxis	Admit to Intensive Care Unit
Severe	Marked progressive swelling, pain with or without local tissue destruction Systemic symptoms such as diarrhea, weakness, shock, or angioedema, and/or pronounced thrombocytopenia or coagulopathy	Yes	IV Fluids Cardiac monitoring Analgesics Follow laboratory parameters Oxygen Vasopressors as indicated Tetanus prophylaxis	Admit to Intensive Care Unit

^aSee Antidotes in Depth: A37 for dosing recommendations.

Since pit viper bites result in injection of venom only about 75% of the time, approximately 25% of bites do not result in envenomation and are considered “dry bites.” Unfortunately, it is impossible to diagnose a dry bite without an extended period of observation, since some patients may have delayed onset of symptoms for as much as 8 to 10 hours following the bite. On occasion, patients may initially present asymptomatic yet go on to develop serious illness. Even for patients who do present with symptoms, it may require a number of hours for the full extent of clinical illness to become evident. As a general rule, however, it may be assumed that envenomation from a pit viper has not occurred if no symptoms develop within 8 to 10 hours from the time of the bite.

Of the North American pit vipers, rattlesnakes are responsible for the most severe clinical presentations. Agkistrodon (cottonmouth and copperhead) bites generally tend to produce less severe local and systemic pathology than rattlesnake bites. Copperhead bites in particular rarely cause systemic symptoms, and pathology is usually limited to soft tissue

swelling without necrosis.⁵⁵ However, serious copperhead envenomations occasionally occur, and at least one death has been reported in association with this species.⁴³

Local reactions. Generally, within minutes after pit viper envenomation, the area around the puncture site becomes swollen and painful, and oozing of blood from the wound may be noted. Edema may stabilize quickly in mild envenomations, but more commonly, edema will gradually worsen over hours. In severe cases, edema may progress to involve an entire extremity within just a few hours. Swelling can worsen for days when untreated, extending proximally to involve the torso following bites to a distal extremity. Rarely, onset of appreciable swelling is delayed for as long as 10 hours. This is most often noted in lower extremity envenomations.

Ecchymosis may develop early at the wound site. Bites to the feet often exhibit a characteristic bluish tinge over the entire dorsal surface of the foot. Toes remain pink and well perfused, allowing distinction of this ecchymosis from cyanosis (Fig. 122–5). In the days to weeks following the envenomation, ecchymosis will often extend or new ecchymosis may develop proximally, even in the absence of significant venom-induced hematotoxicity.

FIGURE 122–5. Rattlesnake bite to the lower leg, with characteristic edema and bluish discoloration of the foot due to ecchymosis.

Erythema may also develop at the envenomation site and sometimes spreads proximally from the wound along lymphatic pathways. Lymphangitic streaks are occasionally noted in the absence of infection.

Hemorrhagic blisters (blebs or bullae) often form at the site of the bite after rattlesnake envenomations. This most commonly occurs after bites to digits but may occur at any bite location or even in dependent areas distant from the bite (Fig. 122–6). Blebs usually do not appear for several hours after the envenomation but can progress for several days. Tissue underlying blebs is often healthy, but extensive bleb development may signify underlying tissue necrosis (Fig. 122–7).

FIGURE 122–6. (A) Hemorrhagic bullae involving the entire digit after rattlesnake bite to the second digit. (B) Hemorrhagic bullae involving the antecubital fossa after rattlesnake bite to the hand. (Copyright © 2002, Department of Toxicology Good Samaritan Regional Medical Center.)

FIGURE 122–7. Dèbridement of hemorrhagic bullae revealed the underlying tissue to be dark and necrotic in this patient.

Myonecrosis is not a feature of most native pit viper envenomations but does sometimes occur. In rare cases fangs may

directly penetrate muscle leading to localized necrosis. With subfascial envenomation there is a risk for compartment syndrome, which could lead to necrosis. Compartment syndrome is very rare following North American snakebite and cannot be reliably diagnosed in envenomed extremities without directly measuring compartment pressures. More often than not envenomation simply mimics a compartment syndrome by producing distal paresthesias, tense soft tissue swelling, pain on passive stretch of muscles within a compartment, and muscular weakness. One study, using noninvasive vascular arterial studies and skin temperature determinations in patients with rattlesnake envenomation, demonstrated that pulsatile arterial blood flow to an envenomed extremity actually increased after envenomation, even distal to the site of envenomation.¹⁵

In addition to local myonecrosis, generalized severe rhabdomyolysis may occur in the absence of impressive muscular swelling. This finding is considered characteristic after envenomation by the Canebrake rattlesnake (*Crotalus horridus atricaudatus*), which was previously classified as a subspecies of the Timber rattlesnake (*C. horridus*). Current prevailing opinion is that they are the same species.^{12,50}

Hematologic toxicity. Venom-induced effects on the hematologic system are common following bites by North American pit vipers, in particular rattlesnakes. Coagulopathy, thrombocytopenia, or a combination of the two, may be present despite a paucity of other local or systemic effects. A decrease in platelet count, as well as decreases in fibrinogen with elevation of prothrombin time (PT), may be mild or modest initially and may either remain so or continue to worsen for several days following the envenomation. Alternatively, severe decreases in platelet counts (in the 5000–50,000/mm³ range) and fibrinogen concentrations (to near zero) with immeasurably high PTs may occur within minutes to hours of crotaline envenomation. A rise in PT generally follows a drop in fibrinogen, as concentrations of clotting factors remain normal in case reports of North American crotaline envenomation with coagulopathy.¹¹ The likelihood of thrombocytopenia or coagulopathy occurring after a given snakebite may depend on the particular species and venom populations present in the geographic area. In the desert southwest, coagulopathy occurs in approximately half and thrombocytopenia in one-third of patients presenting with envenomation.³⁹ Thrombocytopenia appears to be especially common and often severe after the bite of the Timber rattlesnake *Crotalus horridus*.³ The protein crotalocytin that is found in Timber rattlesnake venom causes platelet aggregation and is thought to be at least partially responsible for the thrombocytopenia.

Despite the high rate of hematologic effects following rattlesnake envenomations, the vast majority of patients have no clinical bleeding, even when severe laboratory abnormalities are present. Bleeding appears to be more common when platelets are very low or when both coagulopathy and thrombocytopenia are present and severe.

Systemic toxicity. Clinical findings following most pit viper bites are limited to local tissue damage or hematologic pathology, but systemic symptoms may develop. When present, systemic signs and symptoms are often mild and include nausea, metallic taste, restlessness, and nonspecific weakness. Tachycardia, vomiting, diarrhea, and confusion may also occur. These more significant systemic symptoms have been noted to precede severe systemic toxicity. In the most severe cases, patients quickly develop circulatory shock or airway edema with obstruction, which may be caused by anaphylactoid responses to venom components.

Rarely, patients bitten by crotalids may experience classic anaphylaxis from the venom itself, which may complicate evaluation or mimic a severe systemic reaction to venom. Previous sensitization to venom results in development of IgE antibodies to venom in these patients. This is thought to occur more frequently in patients who have previously experienced a snakebite, but it has also been observed in snake handlers who are thought to be sensitized to snake proteins through inhalation or skin contact. The presence of pruritus and urticaria or wheezing, uncommon with envenomation, should suggest anaphylaxis.

There are rare reports of true disseminated intravascular coagulation (DIC) with spontaneous bleeding along with significant hypotension and multiorgan system failure following rattlesnake bite. In such cases of true DIC, the patient has evidence of organ infarction and hemolysis. This has been reported after intravascular envenomation.¹⁶

Neurotoxicity. Although local tissue destruction dominates the picture of Crotalinae envenomations, neurotoxic effects may also occur. The Mojave rattlesnake (*C. scutulatus*) is best known for its neurotoxic venom. Subpopulations of the Mojave rattlesnake that possess the neurotoxic Mojave toxin may produce weakness, cranial nerve dysfunction, and respiratory paralysis in victims.²⁸ The Timber rattlesnake (*C. horridus*) is noted to commonly cause rippling fasciculations of the skin (myokymia), particularly of the facial muscles.⁴ Fasciculations are reported following envenomation by several other species of rattlesnake, including the Western Diamondback (*C. atrox*), Mojave *C. scutulatus*, and the Southern Pacific *C. o. helleri*.¹³ Fasciculations involving the shoulders, chest wall, and torso are associated with development of respiratory failure.⁵³

Coral Snakes. Coral snake fangs are small and nonmobile, and as a result, bites are less likely than pit viper bites to lead to envenomation. An estimated 40% of patients bitten by a coral snake are subsequently determined to have been envenomed, with rates for the Eastern coral snake species possibly higher.³¹ The venom of the Eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*M. tener*) are more potent than that of the Sonoran coral snake (*Micruroides euryoxanthus*). In fact, there have been no reported cases of serious toxicity after the bite of the Sonoran coral snake, which is found primarily in Arizona and western New Mexico.

Coral snake fangs may not produce easily identifiable puncture wounds. In addition to the absence of a discernable

wound in some victims, coral snake envenomations are characterized by potentially serious neurotoxicity without impressive local symptoms. The effects of envenomation are characteristically delayed for a number of hours. One report described a patient who had an asymptomatic period of 13 hours followed by rapid development of paralysis severe enough to require ventilatory support.³¹ Neurologic abnormalities reported with coral snake envenomation include paresthesias, slurred speech, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and paralysis. The major cause of death is respiratory failure secondary to neuromuscular weakness. Muscle weakness may take weeks to months to resolve completely. With respiratory support, however, paralysis is completely reversible. Pulmonary aspiration is a common sequela in the subacute phase.

Lizards. The rate of envenomation following Gila monster bites is not known, but one case series reported 40% dry bites.⁴⁰ When a *Heloderma* species bites, it may release quickly or it may hang on and “chew.” Multiple reports are documented where Gila monsters were attached to the victim for up to 15 minutes, and in some cases teeth have broken off in the wound.

Pain is immediate following a bite, and local soft tissue edema may develop within minutes. Swelling may extend from the puncture site, though not as commonly or dramatically as occurs following pit viper envenomation. Helodermatid venom does not produce local tissue necrosis, but erythema at the wound site and extension of erythema to an entire extremity is well described. Lymphangitic streaking is also reported.^{18,27,46}

Nausea, vomiting, and diaphoresis may occur following helodermatid envenomation. Patients are often tachycardic and hypotension is common. There are numerous reports of upper airway angioedema developing after bites by both Gila monsters and beaded lizards. There is a single report of a young man developing a myocardial infarction after a Gila monster envenomation.³⁸

Leukocytosis is common following envenomation, with reported white blood cell counts as high as 48,000/mm³.³⁸ Unlike crotaline venom, Gila monster venom does not typically produce abnormalities in platelet counts or clotting factors, although a single report of coagulopathy exists following a Gila monster bite in the patient who also experienced a myocardial infarction.³⁸ It has been suggested that the coagulopathy occurred as a result of endothelial damage rather than direct effect of venom on the hematologic system.⁴⁶

DIAGNOSTIC TESTING

Snakes

Diagnosis of North American snake envenomation is based on a history of a snakebite and presence of clinical signs of envenomation. There are no available laboratory assays for detection of venom in a wound. Although it is possible to measure blood and urine venom antigen concentrations using enzyme-linked immunosorbent assay (ELISA), this is only available in research settings and is not useful for early diagnosis or clinical management of envenomation.

Platelet counts, fibrinogen concentrations, and prothrombin times can be useful in the diagnosis of pit viper envenomation if they are abnormal. However, normal results do not exclude envenomation since thrombocytopenia and coagulopathy do not develop in all patients with pit viper envenomation.

A validated severity score for the objective assessment of crotaline envenomation has been developed and can be useful in a research setting.¹⁷ Its purpose is to assess the clinical condition of patients with snakebite, but it is not intended as a diagnostic tool. Caution should be used when applying this scale because envenomation is a dynamic process and severity can worsen or improve with time, limiting the utility of the score obtained at any given point in time.

Lizards. The diagnosis of helodermatid envenomation is based on the history of a bite and presence of physical examination findings consistent with envenomation. There are no laboratory studies that are available to confirm or exclude the diagnosis, but a complete blood count may reveal leukocytosis.

MANAGEMENT

Snakes

When a patient with a snake envenomation presents for care, the initial objectives are to determine the presence or absence of envenomation, provide basic supportive therapy, treat the local and systemic effects of envenomation, and limit tissue loss or functional disability (Table 122–3). A combination of medical therapy (mainly supportive care and, often, antivenom) and in some cases conservative surgical treatment (mainly débridement of devitalized tissue), individualized for each patient, will provide the best results. In general, the more rapidly treatment is instituted, the shorter the period of disability.

Pit Vipers

Prehospital care. No first aid measure or specific field treatment has been proven to positively affect outcome following a crotaline envenomation. Prehospital care should generally be limited to immobilization of the affected limb,

placement of an intravenous catheter, treatment of life-threatening clinical findings, and rapid transport to a medical facility. Patients who are volume depleted, vomiting, or experiencing systemic symptoms such as diarrhea should be given an intravenous fluid bolus. Hypotension that does not quickly respond to a fluid bolus should be treated with epinephrine.

In the past, various methods have been advocated to prevent systemic absorption of venom after snakebites. All of these methods are either ineffective and delay time to definitive care, or are potentially harmful. Such useless and potentially dangerous therapies include tourniquets, incision and suction, venom extractors, electrotherapy, and cryotherapy.

Pressure immobilization bandages (PIB), which are lymphatic-restricting bandages that are applied to the bitten extremity prior to immobilization with a splint, are not recommended for use in patients with North American Crotalinae bites. A randomized, controlled study of pressure immobilization versus observation in a porcine model with intramuscular injection of *Crotalus atrox* venom showed markedly increased compartment pressures in the pressure immobilization group. All animals died in this study, but the pressure immobilization group showed a prolonged time to death as compared to the control group. With local tissue necrosis being the major morbidity associated with pit viper envenomations in humans, not death, the authors concluded that PIB application cannot be suggested as a routine field procedure.⁹ The American College of Medical Toxicology, along with five other international organizations, released a position statement recommending against use of PIB for North American Crotalinae bites.¹

Hospital care. When a patient presents to the hospital with history of crotaline snakebite, it is important to first determine whether an envenomation has occurred. While most patients do show early evidence of envenomation, absence of symptoms at presentation is not uncommon, and not all asymptomatic patients ultimately have “dry” bites. Patients who present with puncture wounds but without swelling or other evidence of envenomation must be observed for delayed onset of symptoms. Victims of a rattlesnake bite should be observed for 8 to 12 hours after the bite. If no swelling develops and laboratory studies remain normal, the bite is likely “dry,” and the patient may be discharged from medical care. A shorter, 6-hour observation period may be appropriate for copperhead bite victims prior to medical clearance.

Supportive. The initial in-hospital assessment of North American crotaline envenomation should focus on airway, breathing, and circulation. Early airway management with endotracheal intubation should be considered in all patients with evidence of angioedema or with bites to the face or tongue. All patients, regardless of presenting symptoms, should have an intravenous catheter placed in an unaffected extremity and receive a bolus of IV fluids. Patients presenting with cardiovascular collapse should receive large volumes of fluid. An epinephrine continuous infusion, starting at 0.1 µg/kg/min and titrating as needed, is the vasopressor of choice for signs of shock.

The affected extremity should be immobilized in a padded splint in near-full extension and elevated above the level of the heart to avoid dependent edema. Although there are no studies to determine the effect of limb elevation on outcome, the authors believe this to be helpful since it may decrease dependent edema, which contributes to increased pain and physical examination findings concerning for compartment syndrome. The authors maximally elevate affected upper extremities by applying stocking net around the limb and attaching the distal end to a raised IV pole.

Marking the leading edge of swelling with a pen will help to identify progression of edema. A baseline complete blood count, PT, and fibrinogen concentration should be obtained initially and repeated in 4 to 6 hours. Patients who are systemically ill should also have electrolytes, creatinine phosphokinase, creatinine, glucose, and urinalysis checked. An electrocardiogram, chest radiograph, and blood gas may also be indicated in ill patients.

A comprehensive physical examination should be done, with emphasis on vital signs, cardiorespiratory and neurologic status, neurovascular status of the affected extremity, and evaluation for evidence of bleeding. Pain should be treated with opioid analgesics as needed, and tetanus prophylaxis should be addressed. The patient should be reassessed frequently with repeat physical examinations, specifically noting any progression of swelling. This may be accomplished by taking serial circumferential measurements of the involved extremity at multiple points proximal to the wound.

Prophylactic antibiotics are not indicated as studies show extremely low (0%–3%) rates of wound infections.³⁵ There is no indication for corticosteroids or antihistamines in the routine treatment of patients with snakebites, except for treatment of anaphylaxis.

Antivenom. Patients with dry bites or with mild envenomations, such as those who present only with localized swelling that does not progress, do not meet criteria for antivenom³⁴ (Table 122–3). Patients who present with progressive swelling, thrombocytopenia, coagulopathy, neurotoxicity, or significant systemic toxicity are candidates for antivenom therapy. Antivenom given in a timely manner can reverse coagulopathy and thrombocytopenia and halt progression of local swelling. There is no evidence, however, that antivenom can prevent or reverse the development of tissue necrosis, so patients should be informed of the risk of tissue loss. This is most commonly noted with rattlesnake bites to the fingers, which occasionally lead to amputation of the digit despite appropriate treatment with antivenom.

The only currently FDA approved antivenom for North American pit viper envenomation is Crotalidae polyvalent immune Fab (CroFab, BTG). CroFab is an ovine-derived Fab fragment antivenom developed from commonly encountered North American pit vipers (*C. atrox*, *C. adamanteus*, *C. scutulatus*, *A. piscivorus*). CroFab is administered IV in an initial dose of four to six vials reconstituted in 0.9% sodium chloride solution. Patients who present with cardiovascular collapse or other life-threatening toxicity should be treated aggressively with a starting dose of 8 to 12 vials of CroFab.³⁴ The

infusion is initiated at a slow rate for several minutes, and if no signs of an anaphylactoid reaction develop, increased to complete the infusion over one hour. The patient should be reassessed after completion of the infusion for evidence of continued swelling or worsening thrombocytopenia, and, if present, an additional four-to six-vial dose is infused. This process is repeated until control of symptoms is achieved. Fibrinogen and PT may be slower to recover in response to antivenom. If these are the only findings that continue to be abnormal after antivenom, it is reasonable to repeat these studies in 4 hours to determine if redosing of antivenom is necessary. Control is generally considered cessation of progression of swelling and systemic symptoms in addition to improvement in coagulopathy and thrombocytopenia. After control has been achieved, maintenance doses of antivenom are given as two vials every 2 hours for three doses (six total additional vials after control). Although recommended in the package insert for CroFab, maintenance therapy is not routinely administered by all practitioners.⁵ For example, maintenance doses may be unnecessary in the management of copperhead envenomations. Practitioners can learn local practices and recommendations through consultation with regional poison centers. An algorithm for treatment of North American crotaline snakebite is also available online.³⁴ Antivenom therapy is discussed in detail in Antidotes in Depth: A37.

Antivenom administration in children follows the same guidelines as adults, with doses based on clinical presentation and laboratory findings rather than weight. Attention should be paid to total amount of fluid received, and if necessary, antivenom can be reconstituted in a smaller total volume of fluid. Generally, patients with severe snake envenomation have large fluid requirements, and fluid overload is not a problem.

Pregnant patients who meet criteria for treatment should also receive antivenom. Crotalidae polyvalent Fab (ovine) is currently listed as pregnancy category C, but it has been used safely during pregnancy.³² Given the relative safety of this antivenom and the potential for fetal demise after envenomation, a low threshold for treatment should be considered. Fetal and maternal monitoring should be carried out throughout the patient's care.³³

Surgery. Surgery is not routinely indicated following snakebites. An extensive review of the literature failed to identify any evidence to support the use of fasciotomy in the treatment of snakebites.¹⁴ A single case of elevated compartment pressure (55 mm Hg) after rattlesnake envenomation was managed without fasciotomy. The authors treated this patient with antivenom, as well as mannitol and hyperbaric oxygen.²³ When compartment syndrome is suspected, intracompartmental pressures should be measured. It is reasonable to attempt to treat moderately elevated compartment pressures with antivenom initially, but clinical examination and compartment pressures should be followed closely. Just as there is no strong evidence to support the use of fasciotomy, similarly there is a lack of evidence demonstrating that surgery is unnecessary when intracompartmental pressures are high. If the patient develops evidence of limb ischemia or increasing compartment pressures, fasciotomy may be indicated.

Patients with bites to the digit may present with evidence of ischemia. The finger may appear cyanotic or pale, tense, and lack sensation. The small diameter of the digit and limited ability of the skin to expand essentially creates a small compartment. In such cases it may be reasonable to perform a digital dermatomy, where a longitudinal incision is made through the skin on the medial or lateral aspect of the digit in order to decompress the neurovascular structures. Although there are no studies evaluating the efficacy of dermatomy in preventing tissue loss, the authors have seen patients with cyanotic and insensate digits regain color and sensation immediately following this procedure. Dermatomy should not be performed prophylactically in cases of digital envenomation, as most patients have good outcome without any surgical intervention.²⁵

Debridement of hemorrhagic blebs and blisters is often performed to evaluate underlying tissue and relieve discomfort. Some patients may require surgical debridement of necrotic tissue or even amputation of a digit 1 to 2 weeks after the bite. Referral to a hand surgeon is appropriate for patients with evidence of extensive tissue necrosis.

Blood Products. Immeasurably low fibrinogen concentrations, prothrombin times greater than 100 seconds, and platelet counts lower than 20,000 K/mm³ are routinely encountered after rattlesnake envenomation. Such abnormal laboratory results alone should not prompt the clinician to treat with blood products in the absence of clinically significant bleeding. The circulating crotaline venom responsible for the thrombocytopenia and coagulopathy is still present and will likely inactivate any transfused components. For this reason, the mainstay of treatment for crotaline envenomation-induced coagulopathy and thrombocytopenia is antivenom, not blood products. Correction of coagulopathy, thrombocytopenia, and bleeding can frequently be achieved with antivenom alone. Rarely, a patient will have active bleeding, and antivenom alone will not correct the platelets and fibrinogen. In such cases, fresh frozen plasma, cryoprecipitate, packed red blood cells, or platelet transfusions may be required.

In some cases, thrombocytopenia may be difficult, or impossible, to correct with even large amounts of antivenom. The Timber rattlesnake, for example, is known for producing thrombocytopenia resistant to antivenom. The initial correction of platelet counts after treatment may be transient (lasting only 12–24 hours), with thrombocytopenia sometimes persisting for days to weeks after normalization of other coagulation parameters. In the absence of bleeding, thrombocytopenia is a benign, self-limiting disorder, resolving within 2 to 3 weeks of envenomation. It may be best to closely follow patients with resistant thrombocytopenia who are not bleeding, rather than attempt further platelet transfusions or antivenom administration.³⁷

Follow-up care. Hospital stays for patients with uncomplicated pit viper envenomations are typically short, lasting approximately 1 to 2 days³⁹ Upon discharge from the hospital, patients often have residual swelling and functional disability. They may have continued progression of hemorrhagic bullae with underlying necrosis. Patients should have an out-patient follow-up evaluation to ensure wounds are healing appropriately and extremity function is returning. If joint mobility does not return to baseline as swelling resolves, the patient should be referred for physical and occupational therapy.

In a significant proportion of rattlesnake bite patients treated with Crotalidae polyvalent immune Fab antivenom, a return of swelling, coagulopathy, or thrombocytopenia may be noted after initial resolution of the effect after initial treatment with antivenom. This has been termed “recurrence” of venom effect and is attributed to the interrelated kinetics and dynamics of venom and antivenom.^{39,42} Simply stated, Fab antivenom has a clinical half-life shorter than that of venom. Administration of maintenance doses of antivenom is used in an attempt to prevent development of recurrent effects. Maintenance doses appear to be effective in preventing recurrence of local swelling in most cases, but many patients develop hematologic recurrence within 3 to 7 days of antivenom treatment despite administration of maintenance doses. Additionally, patients who never manifested thrombocytopenia or coagulopathy during their hospital presentation may later develop the effect, presumably because of initial “masking” of the effect by early antivenom administration. These recurrent or late hematologic effects have been associated with life-threatening bleeding.³⁰ No risk factors have been identified to predict which patients will develop late thrombocytopenia or coagulopathy.

The most reasonable way to address possible late hematologic effects of crotaline envenomation is careful outpatient follow-up after hospital discharge. Patients with copperhead bites may be followed as needed.^{34,39} The safest approach is to provide careful discharge instructions and consider all patients who have been treated with Crotalidae polyvalent immune Fab antivenom to be at risk for late hematologic toxicity. Patients who use antiplatelet or anticoagulant medications should be continued on these medications only after a careful risk-benefit analysis. Whenever possible the medications should be discontinued until the risk of recurrent or late hematologic toxicity passes. Patients must be warned not to undergo dental or surgical procedures for up to 3 weeks unless platelet and coagulation studies are documented to be normal immediately prior to the procedure. High-risk activities, such as contact sports, should be avoided. All patients should have platelets and coagulation studies measured 2 to 3 days, and again 5 to 7 days, after the last antivenom treatment. If values are abnormal or trending in the wrong direction, the studies should be repeated every few days until normalized. Patients should be advised to avoid surgical procedures and activities that place them at risk for injury. Opinions on when to retreat patients exhibiting late hematologic toxicity with antivenom vary. The general approach of the authors is to retreat any patient with evidence of bleeding, as well as patients with severe isolated thrombocytopenia (platelets $<25,000/\text{mm}^3$) or moderate thrombocytopenia (platelets $25,000\text{--}50,000/\text{mm}^3$) in combination with severe coagulopathy (fibrinogen $<80\text{ mg/dL}$).³⁹ Many clinicians choose to observe patients with isolated coagulopathy cautiously as outpatients rather than to retreat them with antivenom. However, if patients with isolated severe coagulopathy have other risk factors for bleeding, such as use of antiplatelet medications, retreatment with antivenom should be considered.

When the decision has been made to retreat a patient with late hematotoxicity with antivenom, an initial starting dose of two vials is recommended. Late thrombocytopenia appears to be more resistant to antivenom than early venom-induced thrombocytopenia, and it is unclear whether a different mechanism may be responsible for the late effect. It is unknown how much antivenom is needed to reverse late thrombocytopenia or at what dose a patient may be considered “resistant” to antivenom. Patients who have evidence of bleeding with severe thrombocytopenia may require platelet transfusion. Some clinicians have also given steroids to patients who have not responded to antivenom and platelet transfusions, but there is no evidence to support the efficacy of steroids in this setting.

Coral Snakes

As with North American pit viper bites, patients who are bitten by North American coral snakes should be taken to a hospital for definitive medical care as soon as possible. There are no field treatments that have been shown to affect outcome in these patients. Pressure immobilization bandages (PIB) have been shown to delay the systemic absorption of venom from Australian elapid snakes. A swine model of coral snake envenomation suggests that pressure immobilization bandaging may be effective in delaying systemic absorption of venom following coral snakebite.²¹ Patients who present for care after a PIB has been placed should have the dressing left in place until resuscitative equipment and personnel are present and, ideally, antivenom is available. The PIB should be checked to ensure it is not functioning as a tourniquet.

Patients with a history concerning for possible Eastern or Texas coral snakebite should be observed for 24 hours in a monitored unit where resuscitative measures, including endotracheal intubation, can be performed. Since neuromuscular weakness and respiratory paralysis can develop quickly, endotracheal intubation should be considered at the first sign of bulbar paralysis. Traditionally, treatment with Wyeth Antivenin (*Micrurus fulvius*) (equine origin) North American Coral Snake Antivenin (NACSA) has been recommended for all patients in whom there is strong suspicion of coral snakebite, even in the absence of signs of envenomation. This is mainly because paralysis can develop quickly and symptoms may not reverse following antivenom treatment. Approximately 10 years ago Wyeth ceased production of NACSA, creating a shortage of antivenom and prompting many clinicians to take a more conservative approach to treating patients with coral

snakebites. A recent study comparing patients who received empiric treatment with antivenom to patients who were treated when symptoms developed suggests that a conservative approach (waiting for symptoms to develop before administering antivenom) does not result in worse outcomes for patients.⁵⁸ The expiration date of current supplies of NACSA was extended to April 2014.⁵¹ Pfizer is expected to take over production of this antivenom in the near future.

If a patient is symptomatic following a coral snake envenomation, antivenom, if available, is indicated. If antivenom is unavailable, patients may be managed with supportive care alone. Mechanical ventilation may be necessary for many weeks. Acetylcholinesterase inhibitors, neostigmine and edrophonium, have been successfully used to treat patients with South American coral snakebites, but their use should be considered experimental.⁶

Sonoran coral snakes, indigenous to Arizona and California, have never been reported to cause significant toxicity, and bite victims do not require observation in the hospital or antivenom administration.

Lizards. Management of helodermatid envenomation consists of supportive care. There is no antivenom available against lizard venom. Routine wound care should be performed, and the clinician should look for the presence of teeth in the wound. There is no evidence to guide clinicians when deciding whether to administer antibiotics to patients with erythema surrounding and extending from the bite site. Most case reports describing patients with erythema also report empiric use of antibiotics. There are no reports of confirmed infections following these bites.

Patients who are symptomatic following a bite should be attached to a cardiac monitor and have an intravenous catheter placed. Although serious morbidity from lizard bites is unusual, envenomation may be life threatening. Angioedema, other evidence of respiratory compromise, or airway obstruction should prompt endotracheal intubation. Hypotension may require treatment with intravenous fluid boluses as well as vasopressors such as epinephrine. Epinephrine, corticosteroids, and antihistamines may be indicated for the treatment of anaphylactoid reactions.

SUMMARY

- Most native snake envenomations result from bites by Crotalinae species of snakes, also known as pit vipers, and commonly produce local tissue swelling and hematologic toxicity.
- A small percentage of envenomations are due to bites by coral snakes, which are known for producing neurotoxicity without local tissue effects.
- Management of patients with pit viper and coral snake envenomation should focus on aggressive supportive care and specific antivenom when indicated.
- Envenomations by Helodermatid lizards are often associated with local pain, erythema, hypotension, and angioedema.
- Clinicians are encouraged to contact a regional poison control center when a patient presents after a snake or lizard envenomation.

A37 ANTIDOTES IN DEPTH

Antivenom: Snakes (Native [US] Venomous [Crotaline and Elapid])

Anthony F. Pizon and Anne-Michelle Ruha

INTRODUCTION

Definitive management of North American venomous snakebites is antivenom and supportive care. In the past, numerous treatments were advocated to prevent systemic absorption or to neutralize venom. These therapies included tourniquets, incision and suction, venom extractors, electrotherapy, and cryotherapy. All of these treatment modalities are either ineffective, delay time to definitive care, or harmful. The focus of treatment for the snakebite victim is a careful assessment, supportive care, evaluating for signs of envenomation, and ultimately, determining the need for antivenom.

HISTORY

Crotalidae Polyvalent Immune Fab (Ovine)

Historically, Wyeth (Marietta, PA) manufactured Antivenin Crotalidae Polyvalent (ACP) for treatment of crotaline snakebites in the United States. It was a poorly purified whole IgG product derived from horse serum with significant risk for acute and delayed allergic reactions.¹⁶ Wyeth has since stopped production of ACP, and all extant lots have expired. Many physicians still recall the use of this product, but new antivenoms have replaced ACP and have improved the approach to snakebite treatment. In October 2000, the US Food and Drug Administration (FDA) approved Crotalidae polyvalent immune Fab (FabAV), manufactured by BTG International (West Conshohocken, PA). This product is marketed as CroFab. This antivenom is derived from sheep serum and formulated specifically to treat snakebites from US Crotalinae species. It is an effective and less allergenic alternative to the previously manufactured horse serum product from Wyeth.^{16,33}

Antivenin (*Micrurus fulvius*) (Equine)

For decades, Wyeth Laboratories (Marietta, PA) manufactured Antivenin (*Micrurus fulvius*) (Equine), which is more commonly known as North American Coral Snake Antivenin (NACSA), for treatment of envenomations by the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*). Wyeth discontinued production of this antivenom. The last remaining lot (# 4030026) was labeled with an expiration date of October 31, 2008. However, the US Food and Drug Administration extended the expiration date based on stability and potency data to October 31, 2013. Additionally, lot 4030024 has a new expiration date of April 30, 2015.³⁵

PHARMACOLOGY

Crotalidae Polyvalent Immune Fab (Ovine)

Chemistry/Preparation. Crotalidae polyvalent immune Fab (FabAV) is produced by inoculating sheep with the venom of one of the following crotaline snake species: the eastern diamondback rattlesnake (*Crotalus adamanteus*), western diamondback rattlesnake (*Crotalus atrox*), cottonmouth (*Agkistrodon piscivorus*), and Mojave rattlesnake (*Crotalus scutulatus*). The species specific antivenom is then prepared by isolating the antibodies from the sheep serum and digesting the IgG antibodies with papain. The venom-specific Fab antibody fragments are then isolated by affinity purification. This refining process eliminates most of the Fc portion of the immunoglobulin and other potentially immunogenic sheep proteins. Manufacturing specifications require $\leq 1.0\%$ w/w for Fc fragments and $\leq 0.3\%$ w/w for albumin.¹⁴ All four species specific antivenoms are then combined to form the final polyvalent product. The resultant Fab antivenom is less immunogenic and more potent compared to whole IgG antivenoms used previously.^{7,12}

Mechanism of Action. FabAV is comprised of the Fab portion of IgG antibodies directed against the venom from four North American crotaline snake species. The antibodies bind and neutralize venom components. In some cases the antibodies may penetrate tissues and help redistribute the venom from its target tissue.

Pharmacokinetics. The pharmacokinetics of FabAV is poorly studied. Elimination half-life calculations were performed using only three patient samples. From these data, the half-life was estimated between 12 and 23 hours.⁸ Although a similarly prepared and sized ovine Fab product had a volume of distribution of 0.3 L/kg, a systemic clearance of 32 mL/min, and an elimination half-life of approximately 15 hours, these parameters may not apply to FabAV.³⁶

Antivenin (*Micrurus fulvius*) (Equine)

Chemistry/Preparation. NACSA is manufactured by immunizing healthy horses with venom from the eastern coral snake (*Micrurus fulvius*). The horse serum is then purified and concentrated before it is lyophilized for storage. Unlike FabAV, NACSA is a whole IgG product.

Mechanism of Action. The antibodies in this antivenin are directed against the venom of the eastern coral snake. The antibodies bind and neutralize venom components. In some cases the antibodies may penetrate tissues and help redistribute the venom from its target tissue.

Pharmacokinetics. The pharmacokinetics of NACSA are unknown and unstudied.

CLINICAL USE

Crotalidae Polyvalent Immune Fab (Ovine)

Crotalidae polyvalent immune Fab (FabAV) is specifically designed using the venoms of four North American crotalids: the eastern diamondback rattlesnake (*Crotalus adamanteus*), western diamondback rattlesnake (*Crotalus atrox*), cottonmouth (*Agkistrodon piscivorus*), and Mojave rattlesnake (*Crotalus scutulatus*). However, murine lethality studies demonstrate that FabAV has activity against the venom of six other crotaline snake species (*Crotalus viridis helleri*, *C. molossus molossus*, *C. horridus horridus*, *C. horridus atricaudatus*, *Agkistrodon contortrix contortrix*, and *Sistrurus miliaris barbouri*).⁷ In addition, numerous case reports document benefit after envenomation by many other North American crotalids.

Some case reports and anecdotal experience report venom effects resistant to FabAV. For instance, thrombocytopenia may not respond to FabAV after envenomations by the red diamond (*C. ruber ruber*) and the timber (*C. horridus horridus*) rattlesnakes.²⁷ In these cases, the thrombocytopenia often responds to initial doses of FabAV, but a subsequent decline in the platelet count is unaffected by repeat dosing of antivenom. Sometimes severe, platelet counts remain extremely low or undetectable until they rebound approximately a week after the envenomation. In rare cases, despite FabAV therapy, late spontaneous bleeding and laboratory abnormalities may occur beyond 2 weeks.²⁶ Furthermore, patients envenomated by the Southern Pacific rattlesnake (*C. viridis helleri*) may have refractory neurotoxicity unresponsive to FabAV.³¹ In general, FabAV may be used to treat envenomations for all North American pit vipers with expected overall benefit despite the occasional refractory envenomation effect in select species.²³

After an envenomation, the major indications for FabAV administration are (1) progression of swelling, (2) significant coagulopathy or thrombocytopenia, (3) neuromuscular toxicity, or (4) hemodynamic compromise. These indications are vague and allow the clinician the ability to interpret the need for antivenom under varying circumstances. If the prothrombin time is elevated, or the fibrinogen or platelet counts are decreased, antivenom should be administered. Furthermore, antivenom is indicated when patients demonstrate muscle fasciculations, weakness, or shock. Antivenom should not be given prophylactically to individuals without evidence of envenomation. Patients should not be given antivenom for limited localized tissue swelling alone when other signs of envenomation are absent. This may be interpreted as swelling localized to only the bite site or swelling that does not cross a major joint, such as a wrist, elbow, ankle, or knee ([Chap. 122](#)).²³ Nonetheless, the bedside physician should use his or her best judgment based on the severity of local swelling before providing antivenom when no other envenomation signs are present.

When indications are met, antivenom should be administered as soon as possible. Since antivenom will halt but not reverse swelling, it is anticipated that early administration would reduce pain and loss of function associated with a grossly swollen extremity, as compared to delayed administration. Animal studies report decreased mortality when antivenom is given immediately after envenomation.⁷ Similarly, the benefits of antivenom diminish with delayed treatment of even a few hours in animal models.¹² Antivenom will not reverse swelling and tissue necrosis that has already occurred, and tissue necrosis may develop despite antivenom administration. Antivenom has, at least temporarily, reversed systemic effects, coagulopathy, and platelet defects.^{4,9,10,22,33} While no studies exist comparing outcomes of envenomated patients treated with and without antivenom, it is generally agreed that antivenom reduces morbidity in patients with significant crotaline envenomation and in some situations may be a lifesaving therapy.¹⁰ The window of therapeutic efficacy in cases of delayed antivenom administration is unknown.

Antivenin (*Micrurus fulvius*) (Equine)

NACSA is the recommended treatment for envenomation by the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*). This antivenom does not treat envenomations from coral snakes found in Mexico, Central America, or South America. Furthermore, bites by the less virulent Arizona coral snake (Sonoran, *Micruroides euryoxanthus*) typically do not produce significant envenomation requiring treatment with antivenom.³⁴

In the past, prophylactic use of NACSA was recommended for all patients with an assumed or proven coral snakebite, even if asymptomatic.¹⁸ Even if there is little objective evidence to suggest envenomation several hours following a coral snakebite, systemic symptoms can develop suddenly. Therefore, antivenom was traditionally administered to prevent the development of potentially life-threatening envenomation. However, the current shortage of NACSA has prompted clinicians to take a more conservative approach and administer antivenom only after signs of envenomation develop. One study comparing patients who received empiric antivenom treatment to patients treated after symptoms arose suggested that a conservative approach was not inferior.³⁸

Indications for NACSA administration include the development of any signs or symptoms consistent with coral snake envenomation. Coral snake envenomations typically lack significant local tissue injury. Antivenom administration should follow the development of any neurologic abnormalities including, but not limited to, paresthesias, slurred speech, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and paralysis. Since anxiety is often associated with a snakebite, true signs of envenomation must be differentiated from anxiety associated with a snake encounter.

In the absence of antivenom, the mainstay of treatment consists of aggressive supportive care. In particular, respiratory failure resulting from muscle weakness may necessitate intubation and prolonged mechanical ventilation until neurological recovery occurs. Although paralysis is completely reversible, it may take weeks to months to resolve.¹⁸

ADVERSE EFFECTS AND SAFETY ISSUES

Crotalidae Polyvalent Immune Fab (Ovine)

Acute hypersensitivity reactions are the most significant safety concerns when providing antivenom products to patients. Crotalidae polyvalent immune Fab (FabAV) was specifically designed to have reduced immunogenicity. However, both acute and delayed hypersensitivity reactions are still well reported.^{5,6} Urticaria, rash, bronchospasm, pruritus, angioedema, anaphylaxis, and delayed serum sickness all are associated with use of this product.^{9,36} An early study reported acute reactions in 14.3% of patients receiving this antivenom, but more current studies suggest an incidence of 5% to 6%.^{5,10,22} Both numbers are still much lower than those reported for the poorly purified whole IgG antivenoms, but the risk of an acute allergic reaction is still a possibility.

When antivenom is administered too rapidly, nonimmunogenically mediated anaphylactoid reactions may occur as well. Anecdotally, most patients appear to tolerate 4 to 6 vials per hour without developing significant anaphylactoid reactions. If the patient requires rapid administration of antivenom because of the severity of the envenomation, H₁ histamine receptor antagonists and an epinephrine infusion should be readily available in case symptoms develop. Clinically differentiating between anaphylactoid and anaphylactic reactions may be difficult, especially when antivenom is administered rapidly. Regardless, the treatment remains the same.

For acute anaphylactic reactions (which often occur shortly following initiation of even low doses of antivenom), the antivenom should be stopped, and aggressive supportive and pharmacological therapy begun. Intravenous corticosteroids, H₁ histamine receptor antagonists, and epinephrine at 2 to 4 µg/min (0.03–0.06 µg/kg/min for children) can be initiated and then titrated to effect. After the symptoms of hypersensitivity resolve, the antivenom should be restarted only in patients at high risk for significant morbidity or mortality from snake envenomation. In such cases, the antivenom infusion is restarted at 1 to 2 mL/h, while the epinephrine infusion is continued. The antivenom infusion rate can be slowly increased as tolerated. If anaphylaxis recurs, the antivenom should be stopped and the epinephrine infusion increased until symptoms resolve. Antivenom can then be restarted while epinephrine is continued at the higher rate. With constant monitoring of patients at the bedside and careful titration of epinephrine and antivenom infusions, patients with life-threatening envenomation should be able to receive the full antivenom dose. Patients have safely received subsequent doses of antivenom after an acute life-threatening reaction.²⁴

In addition to acute allergic reactions, delayed hypersensitivity syndromes in the form of serum sickness may occur. Although most episodes of serum sickness are mild, this syndrome has not been well studied.¹⁶ Typical cases of serum sickness include urticaria, pruritus, and malaise. Arthralgias, lymphadenopathy, and fever may develop on occasion as well. In rare severe cases, glomerulonephritis, vasculitis, myocarditis and neuritis can occur. Delayed hypersensitivity reactions are poorly studied following treatment with FabAV, but are reported to occur in 16% of patients in two clinical trials.^{1,9} This number may be falsely elevated because all but one of the cases came from a single lot of antivenom that was later found to be contaminated with a high concentration of Fc antibody fragments.¹² One treatment regimen for serum sickness is to give 2 mg/kg of oral prednisone divided into two daily doses and tapered over 2 to 3 weeks. However, other

corticosteroids may be used. Oral H₁ receptor antagonists can be used for symptomatic treatment as well. The vast majority of patients can be managed as outpatients, and most respond favorably to oral antihistamines and corticosteroids.

According to the package insert, a known allergy to papaya or papain is a contraindication to the administration of FabAV only if the risks of allergy outweigh the benefits to the administration of the antivenom.⁸ Patients with known allergy to papaya or papain appear rare. However, patients who are also allergic to latex or a variety of fruits (banana, avocado, kiwi, apricot, chestnut, grape, passion fruit, and pineapple) may have crossreactivity with papain.³⁰ Caution is advised when administering FabAV to any patients with atopy, asthma, or known food allergies.

Antivenin (*Micrurus fulvius*) (Equine)

Acute and delayed hypersensitivity reactions are the most significant safety concerns when providing antivenom products to patients. However, little is published concerning adverse reactions to NACSA. The risk of acute hypersensitivity reactions with Wyeth's other equine-derived antivenom product, ACP, was between 20% and 50%, and the incidence of delayed hypersensitivity reactions increased with increasing doses.^{17,37} The exact incidence of hypersensitivity with NACSA is unknown, but approaches 100% when greater than 40 vials of ACP are administered.²⁵ Despite these concerns, severe allergic reactions to NACSA have not been reported, but this may reflect infrequent use and reporting bias.

Patients with a known horse serum allergy or who have been treated with equine derived antivenoms previously should only be treated with NACSA if there is a significant risk of severe morbidity or mortality. Patients with known horse serum allergies have tolerated equine antivenoms, but they often require more dilute doses of antivenom and pretreatment.^{15,24} Intravenous H₁ receptor antagonists, corticosteroids, and an epinephrine infusion should be started (2–4 µg/min for adults) prior to antivenom administration. The antivenom is then started at a very low rate of infusion, and if tolerated, the rate is increased. If an acute allergic reaction develops, the antivenom is immediately stopped and the epinephrine drip titrated for symptoms. Only after symptoms abate should the antivenom be restarted by carefully titrating both the antivenom and epinephrine drips. With severe allergic reactions, antivenom should only be given for life-threatening envenomations. In most cases with severe allergic symptoms, antivenom should be discontinued and followed with supportive care alone.

PREGNANCY AND LACTATION

Crotalidae Polyvalent Immune Fab (Ovine)

Pregnant patients who meet criteria for treatment should also receive antivenom. FabAV is currently listed as category C, but it has been used safely during pregnancy.¹⁹ In the pre-FabAV era, one review of 30 bites by rattlesnakes, copperheads, and cottonmouths during pregnancy reported 43% fetal demise and 10% maternal mortality.¹³ Therefore, given the relative safety of this antivenom and the potential for significant fetal compromise after envenomation, a low threshold for treatment should be considered. Fetal and maternal monitoring should be carried out throughout the patient's care.²⁰

It is unknown if FabAV is excreted in breast milk.

Antivenin (*Micrurus fulvius*) (Equine)

NACSA currently does not have a pregnancy listing. There are no reports of administration of this antivenom to a pregnant patient. Knowledge of the safety of NACSA in pregnancy is unknown. However, other antivenoms have been used safely in pregnancy, and maternal health is often considered at greater risk due to envenomation than an unknown adverse risk to the fetus as a result of antivenom.³ Considering this, and the severe morbidity associated with coral snake envenomation, pregnant patients who meet criteria for treatment should receive antivenom. It is unknown if NACSA is excreted in breast milk.

DOSING AND ADMINISTRATION

Crotalidae Polyvalent Immune Fab (Ovine)

A thorough medication history including previous treatment with antivenoms should be obtained. A history of asthma, atopy, or food allergies should be carefully considered when weighing the risks and benefits of antivenom for a particular patient. According to the manufacturer, the only contraindication is an allergy to papaya or papain. These conditions should not exclude the use of antivenom if the patient is suffering from a moderate to severe envenomation. Crotalidae polyvalent immune Fab (FabAV) is ovine derived, therefore previous reactions to equine derived antivenoms should not preclude use of this product. In cases of mild envenomation, the risk of allergic reaction to antivenom might outweigh any benefit in this patient population. Antivenom should be administered in a monitored setting where resuscitation can be performed and airway supplies can be quickly accessed. Epinephrine, corticosteroids, and antihistamines should be immediately available in the event of a hypersensitivity reaction. If the patient tolerates initial doses without ill effect, subsequent doses may be

administered in a less monitored setting, such as a medical floor or step-down unit.²³

Antivenom is packaged in vials as a lyophilized powder that must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling the vials will result in dissolution times as rapid as one minute. Adding the greater volume also reduces foaming of the product.^{8,29} The reconstituted antivenom is further diluted into a 250 mL of 0.9% sodium chloride solution and administered as discussed above.

The initial recommended dose is 4 to 6 vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over one hour. Patients who present with cardiovascular collapse or life-threatening toxicity should be treated aggressively with a starting dose of 8 to 12 vials of FabAV.²³ The exact concentration of antivenom is not critical. For children, the total volume of fluid in which the antivenom is diluted can be decreased when necessary.²⁸ No dosing adjustment is required for children or small adults because the amount of venom requiring neutralization is not dependent upon the weight of the patient. On the other hand, there is no evidence to support partial doses or infusions of 1 or 2 vials in minor cases.

In order to avoid serious adverse reactions, the first dose of antivenom is administered cautiously in an escalating rate fashion. No skin testing is suggested. The first dose of antivenom (4–6 vials diluted in 250 mL 0.9% sodium chloride solution) is infused at an initial rate of 10 mL/h while the patient is observed carefully for evidence of hypersensitivity. If no adverse reactions are witnessed, then the rate is doubled every few minutes, as tolerated by the patient, with the goal of infusing the first dose over one hour. If the patient tolerates the initial dose without adverse effects, subsequent doses can be given at a rate of 250 mL/h without need for rate titration.

The total dose of antivenom required to control an envenomation may vary widely, so additional doses may be needed to halt swelling and or reverse coagulopathy or thrombocytopenia. With the introduction of FabAV, “control” was defined as arrest of local tissue manifestations and return of coagulation parameters, platelet counts, and systemic signs to normal. However, clinical experience with the product demonstrated that some patients have venom-induced coagulopathy and thrombocytopenia that is resistant to antivenom treatment.³³ Some authors advocate “control” to mean clear improvement in hematologic parameters rather than complete normalization.³³ This definition may be more realistic for the subset of patients with refractory coagulopathy and thrombocytopenia. After each dose of 4 to 6 vials, prothrombin time, fibrinogen, and platelet counts are measured, and the extent of local injury is reexamined. Multiple doses are often required to achieve control. A retrospective study reported 83% of rattlesnake bites and 98% of copperhead bites obtained control with 12 or fewer vials of FabAV.³⁹ This study emphasizes the need for multiple antivenom control doses in rattlesnake envenomations and typically only one initial dose in copperhead bites in order to gain control. If repeat dosing is necessary to control swelling, but fibrinogen, prothrombin time, and platelets remain normal, then these laboratory studies do not need to be repeated after each additional control dose.

After achieving control, maintenance doses of 2 vials every 6 hours are given, for a total of three doses. Again, the 2 vials are added to 250 mL 0.9% sodium chloride solution and administered over one hour. Because the duration of action of antivenom is less than that of venom, the maintenance doses are provided to preclude recurrence of local manifestations, thrombocytopenia, and coagulopathy. An algorithm for FabAV antivenom administration for treatment of moderate to severe crotaline envenomation is shown in [Fig. A37–1](#). Although recommended in the package insert for CroFab, maintenance therapy is not routinely administered by all practitioners.⁸ For example, maintenance doses may be unnecessary in the management of copperhead envenomations.²³ Consultation with regional poison centers can inform local practices and recommendations.

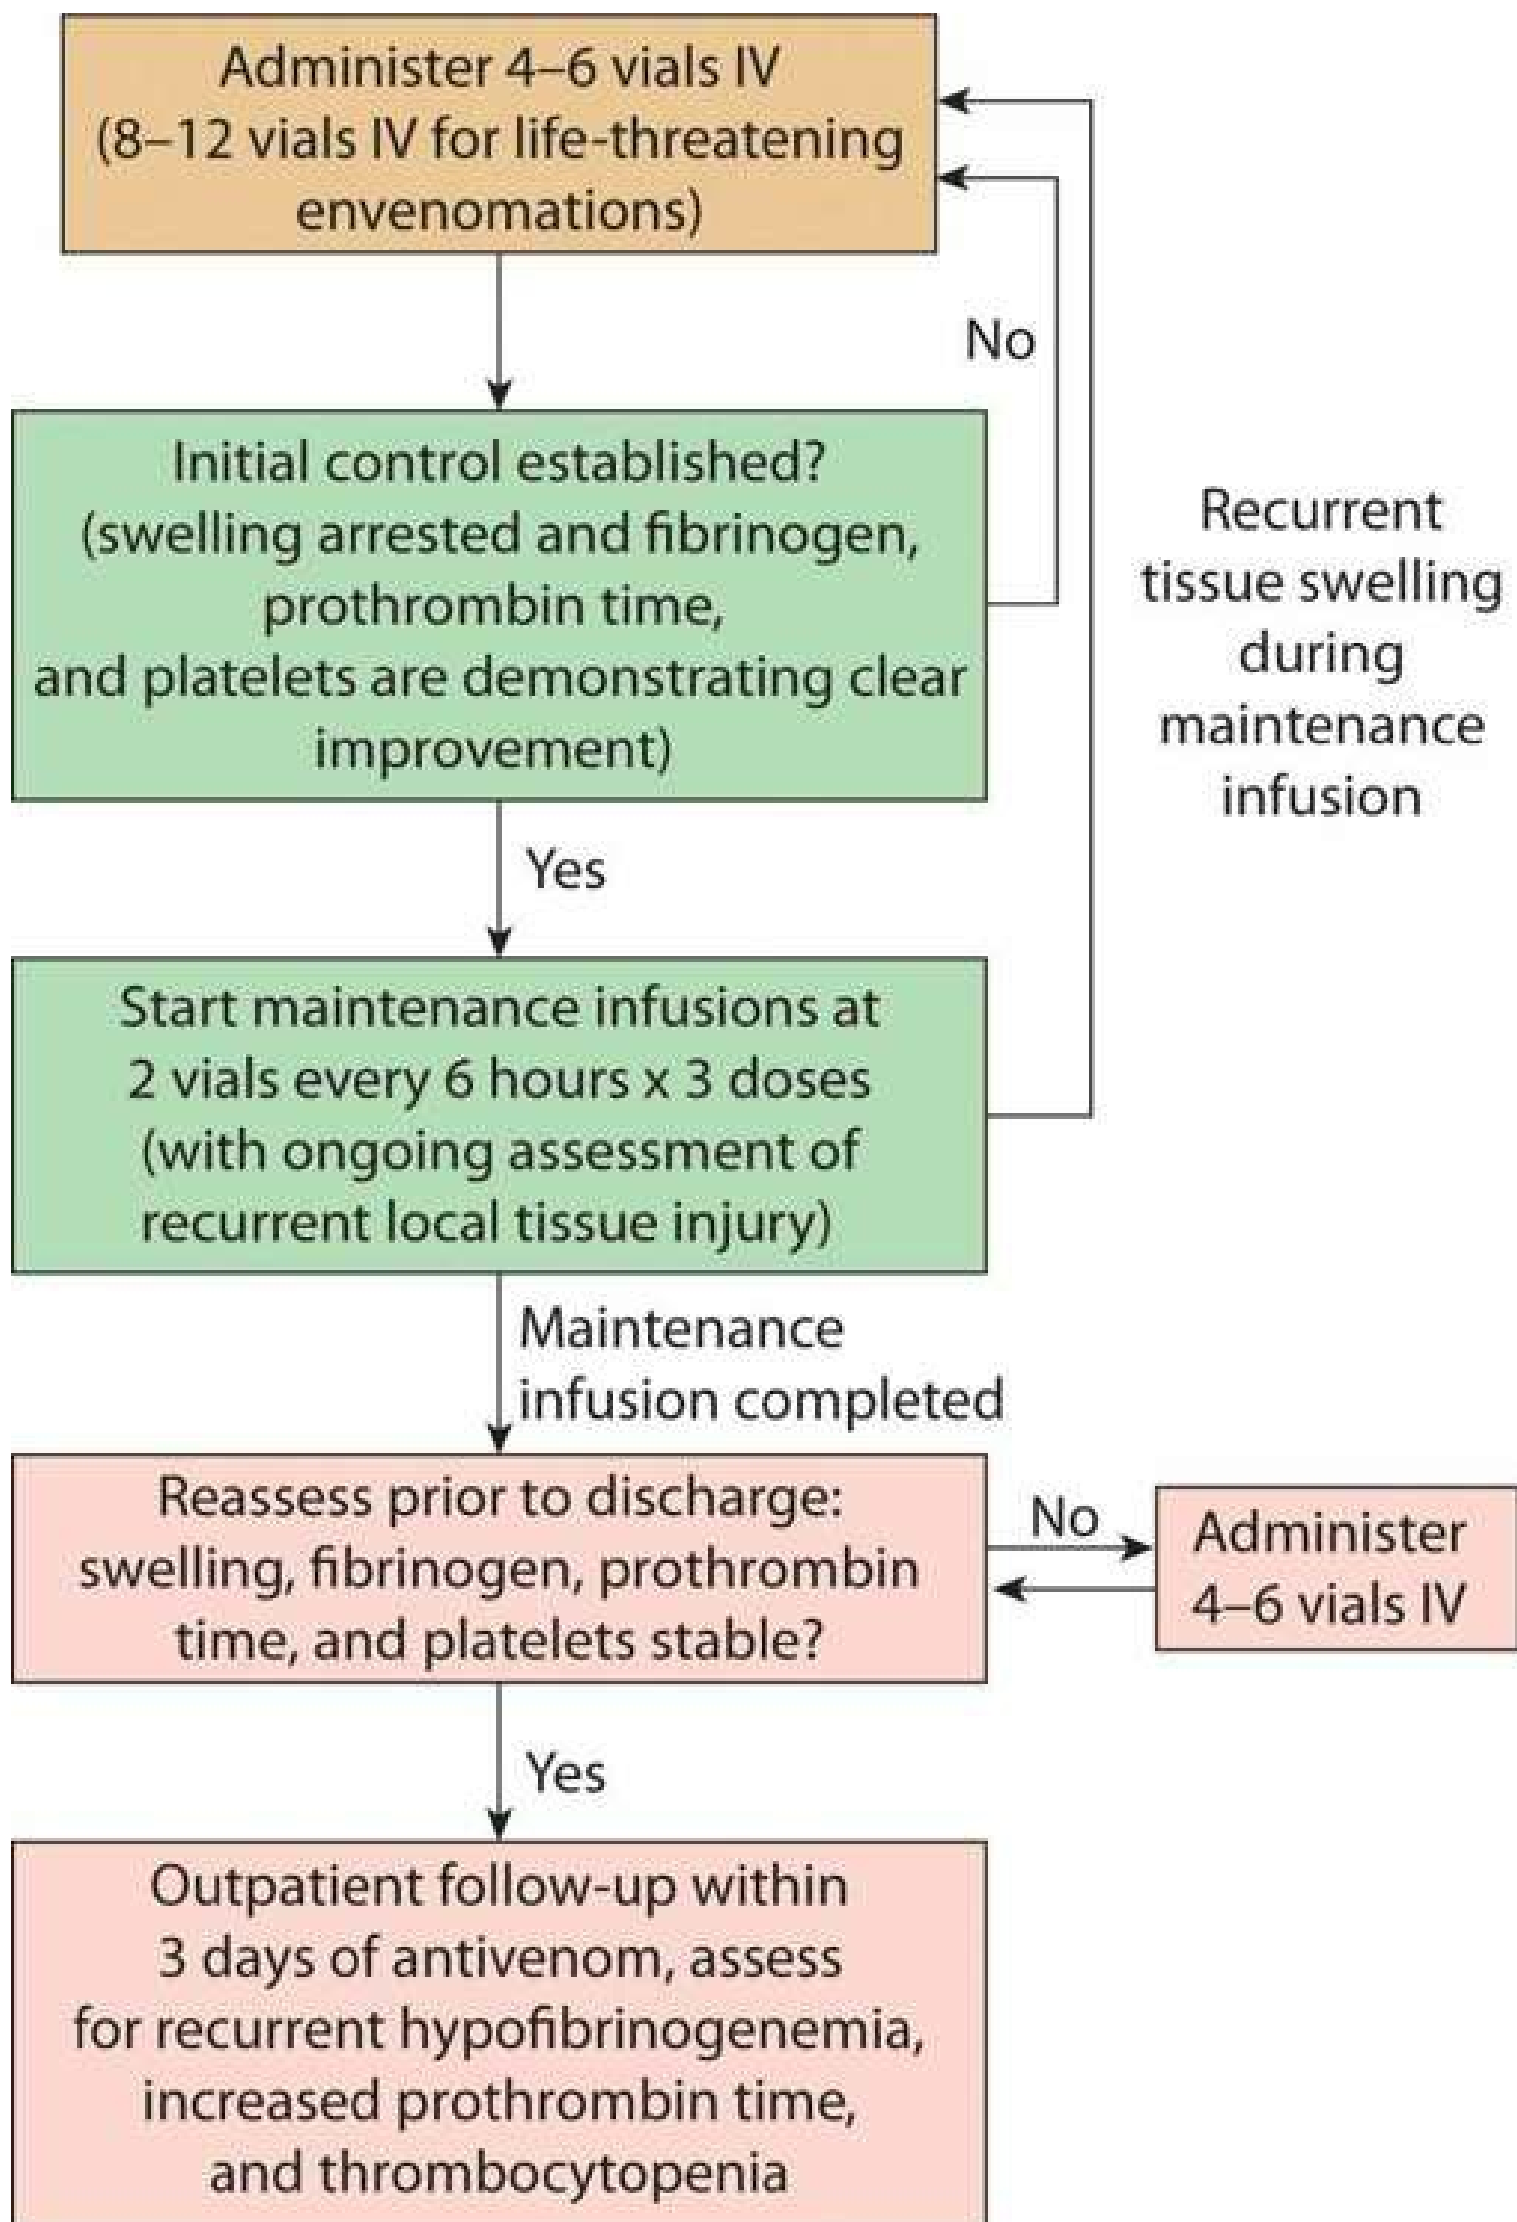

FIGURE A37–1. Algorithm for Crotalidae polyvalent immune Fab administration for treatment of moderate to severe Crotaline envenomation.

Some patients will demonstrate recurrence of swelling during their maintenance infusions. For this reason, close monitoring of extremity swelling should occur for 18 to 24 hours after apparent control has been achieved. If recurrent swelling occurs, additional control doses of 4 to 6 vials should be given until the swelling again becomes controlled. Likewise, despite successful completion of maintenance antivenom doses, patients may develop a recurrence of coagulopathy and or thrombocytopenia. Therefore, all patients should have repeat prothrombin time, fibrinogen, and platelet counts performed 2 to 3 days and again 5 to 7 days after hospital discharge to ensure late recurrent hematologic effects have not developed. One large retrospective study demonstrated new or recurrent hematologic findings in 32% of patients with rattlesnake envenomation.³² Another study suggests recurrence may be as high as 50%.² Close follow-up may be less necessary in copperhead envenomations since hematologic findings are observed less frequently.²¹

Antivenin (*Micrurus fulvius*) (Equine)

Prior to administration of NACSA, a thorough history regarding asthma, atopy, food allergies, and previous use of antivenoms should be obtained. A history of asthma or atopy should be carefully considered when weighing the risks and benefits of antivenom for a particular patient. These conditions should not preclude the use of antivenom if the patient is suffering from a moderate to severe envenomation. Antivenom should be administered in a monitored setting where resuscitation can be performed and airway supplies are immediately available. Epinephrine, corticosteroids, and antihistamines should be immediately available in the event a hypersensitivity reaction occurs.

Antivenom is packaged in vials as a lyophilized powder that must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling (not shaking) the vials will result in dissolution times as rapid as one minute. Adding the greater volume also reduces foaming of the product.^{8,29} The reconstituted antivenom is then diluted into a 250 mL of 0.9% sodium chloride solution and administered as discussed above.

The initial recommended dose of NACSA is 3 to 5 vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over one hour. Additional antivenom doses may be repeated on the basis of the clinical condition. The caveats for crotaline antivenom administration (infusion rate and treatment of allergic reactions) apply to coral snake antivenom, except less antivenom is usually required for coral snakes. Up to 10 vials can be administered, although dosing recommendations are vague.

FORMULATION AND ACQUISITION

Crotalidae Polyvalent Immune Fab (Ovine)

Hospitals with native crotaline species within their region should maintain FabAV at all times.¹¹ Since rapidity of administration is the cornerstone of treatment, attempting to obtain antivenom at the time of an emergency may introduce a significant delay to treatment.

Antivenin (*Micrurus fulvius*) (Equine)

In order to obtain NASCA, contact the local poison center. Poison centers have access to the online Antivenom Index, which is useful when attempting to locate coral snake antivenom.

SUMMARY

- Definitive care of North American venomous snakebites includes antivenom and supportive care.
- If crotalid snakes are endemic to the catchment area of a hospital, Crotalidae polyvalent immune Fab should remain stocked and easily accessible at all times if cost does not make this practice prohibitive.¹¹
- In areas endemic with the eastern or Texas coral snake, supportive care may comprise the only treatment when antivenom is not easily obtained.
- Poison centers have access to the online Antivenom Index, which is useful when attempting to locate antivenom for a coral snake or a non-native snake envenomation. Local zoos may also be useful resources when attempting to locate exotic antivenom. Recommendations for these diverse antivenoms are difficult to make, but available package instructions should be followed, and preparations should be made to treat hypersensitivity reactions (Special Considerations: SC8).

SC8 SPECIAL CONSIDERATIONS

Exotic Nonnative Snake Envenomations

Keith Boesen, Kelly A. Green Boesen, and Farshad “Mazda” Shirazi

HISTORY AND EPIDEMIOLOGY

The incidence of snakebites worldwide is difficult to ascertain, as there is no systematic reporting mechanism. This fact, when combined with the variable degree of confirmation of snakebites, makes the estimation of an accurate number extremely difficult. Attempts have been made utilizing available data from case reports in the literature, hospital records, surveys, and existing reporting systems. Current estimates place the worldwide annual incidence of snakebites as high as 5.5 million.^{11,36} Of these, roughly 50% are thought to be from venomous snakes.⁷ Estimated annual complications include 400,000 amputations³⁶ and approximately 100,000 deaths.^{11,36}

Snakes, while feared by many, are popular around the world as pets. The desire to keep venomous snakes as pets, which is typically illegal in the United States, and the implications throughout the world make the trade of exotic creatures second only to drugs and weapons on the international black market. In fact, the estimated annual worth of this trade in the United States alone is at least \$15 million.¹³

This Special Consideration will discuss the evaluation and management of patients evenomated in the United States by non-native snakes (also known as exotic snakes). From 2007 through 2011, the American Association of Poison Control Centers’ (AAPCC) National Poison Data System (NPDS) recorded 622 nonnative (“exotic”) snakebites, with 250 of these thought to be from a venomous species (Chap. 136).

This same database was reviewed from 1995 through 2004 to characterize the types of exotic snakes involved and circumstances for the envenomations. During that time period, there were 399 exotic snakebites reported, of which 350 were identified by genus and species for a total of 77 different varieties.²⁸ One US expert reported 54 consultations regarding bites from nonnative venomous snakes.¹⁹

In the AAPCC data, the most common family responsible for envenonmations was the viperidae, making up 50% of these bites. Of the Viperidae, almost half of all bites were from four different species: Godman’s Pit Viper, (Bothrops Godmanni), Gaboon viper (Bitis gabonica), Bush master (Lachesis mutus), and the Eyelash Viper (Bothrops schlegeli). The second most common family responsible for envenomations was the Elapidaes, resulting in 30% of US exotic snakebites. Sixty percent were from four different species: Indian Cobra (Naja naja naja), Monocellate Cobra (Naja naja kaouthia), Black Necked Spitting Cobra (Naja Nigricollis), and the King Cobra (Ophiophagus Hannah). The Indian Cobra was the most common snake identified during this study. Of note, there was one Atractaspidae bite (small scaled burrowing asp —Atractaspis microlepidota) and one Colubridae (Boomslang—Dispholidus typus).²⁸

TAXONOMY

The naming of snakes has evolved and the renaming currently continues at a rapid pace due to advances in DNA testing and ongoing research.^{23,24,35} There are 2700 snake species in the world,²³ of which approximately 20% of these are known to be venomous to humans.¹⁶ Venomous snakes are divided into four major families as shown in Table SC8–1.^{12,17,22–24,35}

TABLE SC8–1. Taxonomy of Snakes

Family	Subfamily	Representative Species
Elapidae	Elipinae	Cobras (<i>Naja</i> spp)
		King cobras (<i>Ophiophagus hannah</i>)
		Mambas (<i>Dendroaspis</i> spp)
		Kraits (<i>Bungarus</i> spp)
		Coral snakes (<i>Micrurus</i> spp and <i>Micruroides</i> spp)
	Hydrophiinae	Various sea snakes
	Laticaudinae	Sea kraits
Viperidae	Azemiopinae	Fea's viper is the only species (<i>Azemiops feae</i>)
	Viperinae (old or true vipers)	Russell's viper (<i>Vipera russelii</i>)
		Gaboon viper (<i>Bitis gabonica</i>)
		Saw-scaled viper (<i>Echis carinatus</i>)
		Death adders (<i>Acanthophis</i> spp)
	Crotalinae (pit vipers)	Rattlesnakes (<i>Crotalus</i> and <i>Sistrurus</i> spp)
		Copperheads (<i>Agkistrodon</i> spp)
Atractaspididae		Stiletto snakes (<i>Atractaspis</i> spp)
Colubridae		African boomslang (<i>Dispholidus typus</i>)
		Twig snake (<i>Thelotornis</i> spp)

The Elapidae family has a wide distribution in primarily tropical or arid desert settings in such continents as Asia, Australia, Africa, North America, and South America, with the sea snakes and sea kraits found in the Pacific and Indian Oceans.¹² Possibly the most well known of this family are the cobras, capable of unique characteristics such as hooding or spitting.¹² In the United States, there are three Elapidae snakes; the Eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*Micrurus fulvius tenere*), and the Sonoran coral snake (*Micruroides euryxanthus*).

The Viperidae family, consisting of the three subfamilies (Azemiopinae, Viperinae, Crotalinae), exists throughout the world with a few exceptions. The majority of the snakes in this family can be divided into two main categories: old world vipers (also known as true vipers) and pit vipers.

ANTIVENOM INDEX

The Antivenom Index (AI) was created over 25 years ago as a joint effort of the Association of Zoos and Aquariums (AZA) and the AAPCC for the purpose of creating a database that would contain the location of all nonnative snake antivenoms stored throughout the zoos in the United States. For many years, this was kept in paper format at the Arizona Poison and Drug Information Center and was converted to an electronic database in 2006.

The AI can be searched by the common name or the scientific name of the venomous snake. This search will result in a list of possible snakes that match the description of the searched term. From there, a list of antivenoms active against that genus and species will be displayed, including which zoos stock them and how many vials are available. With this information, and some help from experts or the closest regional poison center, it can be determined where an adequate supply of antivenom exists and what arrangements are necessary to transport the antivenom to the health care facility where the patient in question is receiving care.

Additional information available in the AI includes package inserts for the antivenoms, many of which are translated into English, the expiration dates of the antivenoms, and additional information such as links to various recommendations on the housing, stocking, or administration of antivenoms.

Access to the AI is limited to the AZA and the AAPCC (all poison centers have access). The AZA have the ability to input updated stocking information, while the AAPCC members can view antivenom supplies. To access the AI, contact your local poison center at 1-800-222-1222. Southern Florida is unique in the storage and distribution of exotic antivenoms. The Miami-Dade Fire Rescue Venom Response Program maintains one of the largest repositories of exotic antivenoms for public use in the United States. They work with the local Poison Information Center in Miami for the clinical expertise to facilitate treatment of the envenomated patient.

VENOM TOXICITY

Exotic snake envenomations can and certainly do occur in the United States, most often during feeding or handling the snakes, cleaning the cages, or while milking the snakes for venom.^{19,34} The most common exotic envenomation between 1995 and 2004 involved male owners bitten in a private residence.²⁸ Of all bites that occurred between 1995 and 2004, 80% were the result of an Elapidae or Viperidae snake.²⁸ The venom components from these two families can be classified as neurotoxic, hemotoxic, and or myotoxic.^{5,15,34}

The venom from the Elapidae is associated with neurotoxic effects. Signs and symptoms consistent with neurotoxicity include blurred vision, paresthesias, ptosis, paralysis of facial muscles, difficulty swallowing, respiratory paralysis, and generalized flaccid paralysis.³³ The venom from the Viperidae is more commonly associated with hemotoxicity and myotoxicity, although some species also have neurotoxic effects. The hematologic signs and symptoms associated include petechiae, purpura, ecchymosis, or bleeding and changes in blood coagulation parameters, including platelets and fibrinogen, as well as prothrombin and partial thromboplastin time abnormalities. The activity of Viperidae venom on the clotting cascade occurs throughout the cascade, resulting in varying degrees of severity ([Chap. 60](#)). The signs and symptoms of myotoxins are consistent with local tissue injury and destruction, including swelling, necrosis, and blebs, and are accompanied by elevations of creatine kinase and aminotransferases with possible impairment of kidney function. While there are some classic differences in the presentation between snakes from the Elapidae and Viperidae families, it is important to note that there can also be similarities based on tremendous venom variability found from species to species and in snakes within the same species.¹⁵

CLINICAL PRESENTATION AND INITIAL MANAGEMENT

It is always important to consult with an expert to help identify the snake and determine specific signs, symptoms, and treatment options. Experts can be found within the AAPCC by calling 1-800-222-1222, or a local zoological society or serpentarium.

The clinical presentation of patients with exotic snake envenomation is extremely variable as the sequelae depend largely on the type of species involved and the same factors that influence the outcome of patients envenomated by better understood local snakes; premorbid condition of the individual, location of the bite, dose of venom delivered, and delay to health care. Local poison centers or regional experts may be familiar with species kept in area zoos as part of an emergency response system for treatment of zoo workers. People who maintain these animals as pets and subsequently are envenomated while handling become more difficult to treat. Several basic steps can be followed in initial management of these patients as outlined in [Table SC8–2](#).^{15,34}

TABLE SC8–2. General Approach to a Patient with an Exotic Snake Envenomation

Immobilize the bitten limb in a dependent position and rapidly transport the patient to a medical facility. If the eye is exposed, irrigation with water should be initiated.

Determine the time and location of bite, and mark the borders. Follow and mark the progression overtime.

Determine the species responsible for the bite. If the bite occurred at a zoo, the zoo may have a written plan for management of the specific species ready to accompany the patient (often a zoo employee) that includes the name of species, appropriate first aid, other management guidelines, and any antivenom that is available. Patients who own exotic snakes may know the identity but may use misleading or inaccurate common names. In which case, it may be necessary to contact a local herpetologist, who often can be found through the PCC, to identify the snake.

Standard resuscitation techniques are indicated for cardiovascular or respiratory failure. If there is massive extravasation or hypotension occurs, volume repletion will be necessary.

Physical examination should include signs of local envenomation (pain, swelling, bleeding, and bruising), painful and tender enlargement of lymph nodes, hypotension, spontaneous bleeding, ptosis, and myalgias. Laboratory assessment should include a complete blood count, coagulation profile, electrolytes and kidney function, creatine kinase, aminotransferase, urinalysis for blood and myoglobin, and an ECG.

Begin the process of locating, obtaining, and receiving permission to administer antivenom, even if it is unclear that foreign antivenom will be available or required.

Prepare for life threatening anaphylaxis if foreign antivenom is to be administered.

Due to uncertainties in prediction of clinical evolution and severity of symptom presentation, close monitoring in an intensive care unit is preferred for all patients with exotic envenomations. This will allow for appropriate clinical and laboratory monitoring specific to the needs of the patient. A minimum of 24 hours of hospital observation is indicated to assess delayed evolution of signs or symptoms.

Zoological and Exotic Antivenoms

Hospitals in the United States are not permitted to stock antivenoms for exotic snakes that are not produced for the US market and have not gone through the Food and Drug Administration (FDA) process for drug sale and administration. Zoos are permitted to stock antivenoms for the species of snakes locally housed for the purpose of treating an unintentional exposure. When zoological staff import antivenom from other countries, they must work with the FDA and the Centers for Biologics Evaluation and Research (CBER). The zoo facility is required to complete an Investigational New Drug (IND) Application, assign one or more local physicians who may administer the antivenom, record the name of each product and associated lot numbers, retain copies of the package insert for each product, and complete a statement that the antivenom is being imported solely for emergency use and will not be resold.³⁰ In addition, a Statement of Investigator must be prepared if any changes to the list of approved personnel for administration of the antivenom occur. When the antivenom is administered, a complete case report must be submitted to the director of CBER.

While zoos are permitted to have antivenom stocked at the facility, a recent study demonstrated that of the 106 zoos and 19 aquaria whose representatives responded, only 33 facilities stocked antivenom.³² In the 10 years prior to the study, these facilities reported a total of 39 separate incidents associated with venomous animals. It is unclear why so few facilities with potential for employee exposure do not carry the antivenom required for their local species, as it is possible that a commercially available product could prove essential. Most facilities reported some internal process to respond following an envenomation, including coordinating with the regional poison center, the local emergency medical services, and a local hospital, or have internally developed protocols.

The American College of Medical Toxicology (ACMT) recommends that a zoo or facility that houses exotic snakes have a written plan for management of an envenomation.¹ A study published in 2012 reviewed and tested the effectiveness of an emergency operation procedure.²¹ Zoo Atlanta, the Georgia Poison Center, and the Grady Health System established a procedure to manage an envenomation due to any of the 13 species of snakes housed at the zoo. All three organizations participated in the simulated drill and were evaluated on the functional aspects of coordinating patient care from the time of envenomation through stabilization. In this scenario, all personnel involved were previously alerted to the drill and had additional training as to what was to be expected. Even in this “best case” scenario that included preparation for a patient with an exotic envenomation, problems were still encountered. For instance, the protocol given to the hospital personnel lacked details about specific signs and symptoms expected, clear instructions for antivenom indication, and specific dosing and reconstitution instructions for the antivenom. There were also some general problems with personnel coordination. This study highlights the importance of having a plan in place prior to the emergency that includes the zoo facility, a regional poison center, and the treating institution.

Hospital Use of Exotic Antivenoms

Because exotic antivenoms are not readily available, it may be difficult to obtain the species specific correct antivenom in the appropriate amount. The local poison centers become a critical resources during this time. Often they can locate the closest supply and coordinate delivery. In the case of an envenomation at a zoo, the appropriate antivenom may arrive with the patient. In the case of the exotic snake owner, the poison center may help facilitate borrowing antivenom from local sources, such as zoos, known to stock the antivenom for emergency use. If there are no local sources, the poison center staff can easily access the AI to locate the closest available stock of antivenom. In one case report, it took a regional poison center 5 hours to locate and organize airborne delivery of the appropriate antivenom to the treating facility.¹³ A similar report described a 3 hour delay to administration even when the antivenom was present in the local zoo.⁹ During that delay, the patient required intubation.

Once brought to the facility, a series of steps must occur prior to the patient administration of the non FDA approved antivenom. The treating physician should contact the FDA to obtain approval to administer the antivenom as an IND under emergency use.²⁹ Contact numbers can be found at

<http://www.fda.gov/BiologicsBloodVaccines/DevelopmentApprovalProcess/InvestigationalNewDrugINDorDeviceExempt>

In addition, the treating physician will need to obtain informed consent from the patient prior to administration. Since the antivenom is considered an investigational product, both the Institutional Review Board (IRB) and Drug and Formulary Committee must be notified and provide approval. Many IRBs have emergency processes to expedite such a request. If such approval cannot be obtained in a clinically relevant time, the IRB must be notified of the emergency treatment within 5 working days of the administration.^{1,21} The physician must also complete the appropriate IND paperwork (Form FDA 1571) and submit a comprehensive case report.³⁰

In addition to the legalities involved in using an investigational product, there are significant operational and logistical issues necessary to assure appropriate preparation of the product. The pharmacy department should be notified as soon as possible to allow the staff time to begin researching preparation instructions. Clinical pharmacists provide additional support for both the treating physician and drug preparation aspects in many emergency departments.²¹ The utilization of such individuals can greatly facilitate the medication preparation.

The package insert for the specific antivenom will be most helpful for the pharmacist in the preparation process. Specific instructions on diluents, storage, light or heat sensitivities, compatibility, and rate of administration are usually found in the package insert. If the specific antivenom product is known in advance, the pharmacist can begin to research these issues. Many package inserts are found in the Antivenom Index (AI) and can be obtained with the help of the regional poison center. However, not all package inserts are in English, and some must be translated or a translated copy must be located.¹⁶ Once preparation has begun, reconstitution of the antivenom can take minutes to hours to completely dissolve all the lyophilized particles. In addition to preparation, there is often a significant amount of documentation required when dispensing an IND approved drug. Having knowledge of the required procedure will expedite the administration of the antivenom.

Other Therapies

In principle, snake venoms should have some commonality, as they share the purposes of immobilizing or killing prey and beginning the digestive process, and have some common genetic linkage. In practicality, many venoms from snakes found from diverse area of the globe share constituents or antigenic characteristics.^{4,6,27,37} It may therefore be possible to use antivenoms derived against specific snakes in the treatment of envenomation from other snakes with related venoms. FDA approved coral snake antivenom was used in an experimental model of nonnative elapid envenomation.²⁶ Similarly, FDA approved crotalid antivenom demonstrated efficacy against mice treated with venom from *Crotalus durissus terrificus*, *Bothrops atrox*, and *Bitis gabonica*.^{18,25} In fact, a single case report demonstrates utilization of this principle of cross reactivity when a patient envenomated by *C. durissus terrificus* was successfully treated with US FDA approved CroFab.¹⁴ Such cross-reactivity should never be assumed based on common or taxonomic identification. The manufacturer of CroFab has listed experimental cross-reactivity with a number of species in the AI (Table SC8–3). The clinical decision to use CroFab for a patient envenomated by a non-US species of snake with known experimental cross-reactivity should be based on the severity of envenomation, the availability of species specific antivenom, and the risks associated with administration of species specific antivenom versus the risks of CroFab administration (Antidotes in Depth: A37).

TABLE SC8–3. Experimental Cross Reactivity Between CroFab and Nonnative Snakes^a

Genus	Species and Sub Species	Common Name	Natural Habitat
<i>Akistrodon</i>	<i>bilineatus bilineatus</i>	Cantil, common cantil, Mexican moccasin, tropical moccasin, Mexican cantil	Mexico and Central America
	<i>bilineatus howardgloydi</i>	Castellana	Honduras, Nicaragua, and Costa Rica
	<i>bilineatus lemosespinali</i>	Cantil, Mexican moccasin	Mexico and Central America
	<i>bilineatus russelii</i>	Cantil, common cantil, Mexican moccasin,	Mexico and Central America
	<i>bilineatus taylori</i>	Taylor's cantil, ornate cantil	Mexico
<i>Bothriechis</i>	<i>aurifer</i>	Yellow-blotched palm-pitviper, Guatemalan palm viper	Mexico and Guatemala
	<i>bicolor</i>	Guatemalan palm-pit viper, Guatemalan tree viper	Mexico, Guatemala, and Honduras
	<i>rowleyi</i>	Mexican palm pit viper	Mexico
	<i>schlegelii</i>	Eyelash viper	Central and South America
<i>Bothrops</i>	<i>asper</i>	Fer-de-lance	Mexico and South America
<i>Crotalus</i>	<i>basiliscus</i>	Mexican west coast rattlesnake, Mexican green rattler	Mexico
	<i>cerastes cerastes</i>	Sidewinder, horned rattlesnake, sidewinder rattlesnake	US and Northwestern Mexico
	<i>cerastes cerrobombus</i>	Sonoran Desert sidewinder, Sonoran sidewinder	US and Northwestern Mexico
	<i>durissus durissus</i>	South American rattlesnake, tropical rattlesnake	South America
	<i>durissus totonacae</i>	Totonacan rattlesnake	Northern Mexico
	<i>durissus tzabcan</i>	Middle American rattlesnake, Central American rattlesnake, tzabcan	Mexico and Central America
	<i>eryx eryx</i>	Baja California rattlesnake, Lower California rattlesnake	US and Northwestern Mexico
	<i>exsul (Ruber)</i>	Red diamond rattlesnake, red rattlesnake, red diamond snake	Baja California, Mexico
	<i>exsul exsul (Ruber)</i>	Red diamond rattlesnake, red rattlesnake, red diamond snake	Baja California, Mexico
	<i>intermedius gloydi</i>	Oaxacan small-headed rattlesnake	Mexico
	<i>lunomii</i>	Autlan rattlesnake	Mexico
	<i>lepidus cantaneri</i>	Rock rattlesnake	US and Mexico
	<i>lepidus klauberi</i>	Banded rock rattlesnake, green rattlesnake, green rock rattlesnake	US and Mexico
	<i>lepidus lepidus</i>	Rock rattlesnake, green rattlesnake, blue rattlesnake	US and Mexico
	<i>lepidus moalesus</i>	Durango rock rattlesnake	Mexico
	<i>lepidus morulus</i>	Rock rattlesnake	Mexico
	<i>mitchelli angelesensis</i>	Angel de la Guarda Island speckled rattlesnake	Angel de la Guarda Island in the Gulf of Mexico
	<i>mitchelli mitchelli</i>	Speckled rattlesnake, Mitchell's rattlesnake, white rattlesnake	US and Mexico
	<i>mitchelli muertensis</i>	El Muerto Island speckled rattlesnake	El Muerto Island Mexico
	<i>mitchelli pyrrhus</i>	Southwestern speckled rattlesnake, Mitchell's rattlesnake	US and Mexico
	<i>molossus estabaniensis</i>	San Esteban Island rattlesnake	San Esteban Island Mexico
	<i>molossus molossus</i>	Northern black-tailed rattlesnake, green rattler	US and Mexico
	<i>molossus nigrescens</i>	Mexican black-tailed rattlesnake	US and Mexico
	<i>molossus oaxacae</i>	Oaxacan black-tailed rattlesnake	Mexico
	<i>polystratus</i>	Mexican lance-headed rattlesnake, lance-headed rattlesnake	Mexico

<i>Ophryacus</i>	<i>undulatus</i>	Mexican horned pitviper, undulated pit viper	Mexico
<i>Porthidium</i>	<i>dunni</i>	Dunn's hognosed pitviper	Mexico
	<i>godmani</i>	Godman's montane pitviper, Godman's pit viper	Mexico and Central America
	<i>hespere</i>	Colima hognosed pitviper	Mexico
	<i>nasutum</i>	Rainforest hognosed pitviper, horned hog-nosed viper	Mexico, Central America, and South America
	<i>yucatanicum</i>	Yucatán hognosed pitviper	Mexico
<i>Sistrurus</i>	<i>novus</i>	Mexican pigmy rattlesnake, Mexican pygmy rattlesnake	Mexico

*"Cross reactivity" defined here as experimental evidence supplied by the manufacturer to the Antivenom Index. While clinical evidence of benefit is lacking, use of Crofab can be considered in these envenomations based on a risk-to-benefit analysis when species specific antivenom is lacking, delayed, or contraindicated (due to allergy), and the envenomation is a risk to life or limb.

The venom of many neurotoxic snakes interferes with neuromuscular transmission similar to neuromuscular blockers used in clinical medicine (Chap. 69). Neostigmine and other cholinesterase inhibitors increase the LD₅₀ of animals treated with *Naja haje haje* venom.¹⁰ Additionally, case reports and case series suggest a benefit of neostigmine with or without atropine in humans suffering neurotoxic snake envenomation.^{3,8,20,31} In these reports, patients typically received 0.5 to 1 mg of neostigmine IV immediately following pretreatment with 0.5 to 0.6 mg of atropine IV. In some cases, this is repeated

every 10 to 30 minutes based on response. Unfortunately, this benefit is not universal² and may be dependent on a number of factors, including differences in the mechanism of neuromuscular blockade between snake species. However, since the complications of atropine and neostigmine at these doses are small and there is a suggestion that they may reverse neuromuscular blockade, administration may be indicated if antivenom is unavailable or delayed. Further guidance can be found in Chap. 69 and in Table 69–5.

It is important to remember that there is a wide variation in the standards for preparation of antivenoms around the world. While many products are highly purified antibody fragments, some continue to use whole immunoglobulins that maintain the risk for anaphylaxis. Prior to antivenom administration, preparations must be made to treat life-threatening anaphylaxis. The appropriate level of nursing care and monitoring should be available, IV access should be secured, typical drugs (epinephrine, corticosteroids, antihistamines) and airway management tools should be present at the bedside.

SUMMARY

- Many venomous snakes are available in homes and zoos far from their native habitats.
- It is essential to develop sophisticated systems of care in collaboration with poison centers and zoos assuring preparedness for worker or hobbyist injury.
- The use of internationally prepared antivenom may be life-saving and hazardous. The risks can be limited by understanding the risks and benefits of available internationally prepared antivenoms.
- The Antivenom Index, available to poison centers and the AZA, provides invaluable information about matching an antivenom to a particular snake, location of antivenoms, package inserts, and often English translations of foreign package inserts.
- The use of antivenoms not FDA approved must follow the rules for an IND.
- FDA approved antivenoms may have cross reactivity against some nonnative snakes.

M. OCCUPATIONAL AND ENVIRONMENTAL TOXINS

CASE STUDY 11

History A rapid response team (RRT) was called to the endoscopy suite because a patient developed shortness of breath and decreased oxygen saturation. On arrival, the responders found a 55 year-old man with the following vital signs: blood pressure, 166/112 mm Hg; pulse, 142 beats/min; respiratory rate, 40 breaths/min; oxygen saturation, 87% on 4 liters/minute of oxygen via nasal cannula. The man had a history of Barrett's esophagus and obstructive sleep apnea (OSA) and had to undergo periodic upper gastrointestinal endoscopy as a screening procedure for cancer.

The gastroenterologist who called the RRT reported that the patient had no complaints during the pre-procedural time out and that the following vital signs had been recorded: blood pressure, 142/88 mm Hg; pulse, 88 beats/min; respiratory rate, 16 breaths/min; tympanic temperature, 97.6°F (36°C); and oxygen saturation, 99% on room air. Just prior to administration of conscious sedation, the patient became uncomfortable and complained of shortness of breath. Within a few minutes his vital signs deteriorated and he became cyanotic.

Immediate Assessment and Management The patient was immediately given high flow oxygen via a 100% nonrebreather mask, and although his respiratory rate and pulse improved somewhat, his oxygen saturation remained between 86% and 88%. Physical examination was notable for an ill appearing man who could only speak in short sentences. Although he denied chest pain, review of systems was positive for headache and nausea. His skin and nailbeds were cyanotic, his chest was clear, and his heart was regular and tachycardic without extra sounds. The patency of his intravenous line was confirmed, and an electrocardiogram was obtained and showed sinus tachycardia without ST segment or T wave changes suggestive of ischemia or infarction. When he failed to respond to supplemental oxygen, he was moved to the emergency department (ED).

On arrival to the ED, the following vital signs were obtained: blood pressure, 152/104 mm Hg; pulse, 122 beats/min; respiratory rate, 32 breaths/min; tympanic temperature, 97.8°F (36.5°C); oxygen saturation, 88% on 100% oxygen; and end tidal CO₂, 28 mm Hg.

What Is the Differential Diagnosis? This patient presented with hypertension, tachycardia, tachypnea, cyanosis, and decreased oxygen saturation. The most common causes for these findings are cardiac and pulmonary disease. Hypoxia and cyanosis in a normal environment (breathing a normal FiO₂) can result from a shunt, ventilation-perfusion mismatch, diffusion abnormalities, or pump failure (Chaps. 17 and 29). The absence of underlying heart disease, unremarkable electrocardiogram, pulse and blood pressure that is adequate for tissue perfusion, and clear chest examination essentially excludes these disorders, although laboratory and radiologic confirmation should be obtained (see following sections). When cardiac and pulmonary disorders are excluded, dyshemoglobinemias should be considered, specifically methemoglobinemia and sulfhemoglobinemia (Chap. 127).

What Immediate Diagnostic and Therapeutic Interventions Are Indicated? The patient was maintained on 100% oxygen, and bilevel positive airway pressure (BiPAP) was started while preparations were made for endotracheal intubation. Reasonable initial testing would include a chest radiograph, bedside echocardiogram, and an arterial blood gas (ABG) analysis. In many sections of this book the relationship between a venous blood gas (VBG) and an ABG are discussed (Chap. 29). While under most clinical circumstances a VBG is adequate, when evaluating a patient with decreased oxygen saturation an ABG is preferred, as the VBG will nearly always demonstrate desaturation as oxygen is extracted across the tissue capillary bed.

A chest radiograph showed no cardiac or pulmonary disease, and an ABG was obtained. The resident commented that while she was certain that the blood was obtained from an artery, it looked dark as if it were venous blood. The results demonstrated the following: pH, 7.32; PCO₂, 33 mm Hg; PO₂, 426 mm Hg; with an oxygen saturation of 100%. The results were interpreted as a primary metabolic acidosis with respiratory compensation (respiratory alkalosis). This corresponded to a serum bicarbonate concentration of approximately 16 mEq/L (Chap. 19) and reinforced the clinical impression that the patient was significantly ill.

What Rapid Clinical and Laboratory Analyses Can Confirm the Diagnosis? The combination of cyanosis with a low oxygen saturation by pulse oximetry, failure to respond to supplemental oxygen, dark colored blood, and a normal or high PO₂ on the ABG is essentially diagnostic of methemoglobinemia or sulfhemoglobinemia (Chaps. 29 and 127). When methemoglobinemia is suspected, the color of the blood is related to the methemoglobin level (Fig. CS11-1). While confirmation can and should be obtained via cooximetry analysis of either venous or arterial blood, the clinical information above is sufficient to initiate treatment if cooximetry is either unavailable or delayed.

FIGURE CS11-1. The relationship between methemoglobin level and blood color. This figure demonstrates the relationship between methemoglobin level and the color of blood. If anticoagulated blood is placed on a white background, the methemoglobin level can be estimated accurately by comparison with the scale. It is important to note that while normal anticoagulated venous blood will oxygenate spontaneously (become more red over time) if exposed to room air, methemoglobin is incapable of extracting oxygen from air and will remain dark over time. (Reproduced with permission from: Shihana F, Dissanayake DM, Buckley NA, Dawson AH: A simple quantitative bedside test to determine methemoglobin. *Ann Emerg Med.* 2010;55:184–189. Copyright Elsevier.)

Further Diagnosis and Treatment Venous blood sent for cooximetry revealed: total hemoglobin, 14.6 gm/dL; oxyhemoglobin, 52%; deoxyhemoglobin, 6%; and methemoglobin, 43%. The patient was given 100 mg of methylene blue by slow intravenous administration (Antidotes in Depth: A42). Within about 5 minutes of starting the infusion, his oxygen saturation by pulse oximetry dropped to 64% without a change in his vital signs. Over the next 15 minutes his oxygen saturation gradually increased to 99%, and his respiratory rate, heart rate, and blood pressure normalized. His shortness of breath resolved. A repeat methemoglobin level taken 30 minutes after the end of the methylene blue administration was 3%. The patient remained well.

Further discussion with the gastroenterologist revealed that there were concerns over the patient's history of OSA and the potential complications of procedural sedation, so extensive use of topical anesthesia was attempted prior to the procedure. The medical administration record demonstrated that the local anesthetic chosen contained benzocaine (the most common cause of acquired methemoglobinemia in hospitalized patients), although the exact dose delivered was not documented. Since the generation of methemoglobin following benzocaine administration is dose dependent and occurs more slowly (peak effect is delayed several minutes) than the rate of anesthesia (peak anesthesia in 15–30 seconds), it is easy to conceptualize how a patient can be given an overdose of benzocaine when the appropriate time for maximal anesthesia is not taken before administering a repeat dose. Both the patient and physician were educated on the risks of topical anesthetics, and anesthesia was consulted to assist with airway management and sedation during his rescheduled endoscopy. Two weeks later he returned for his procedure, which was successfully accomplished following combined therapy with topical lidocaine and ketamine for procedural sedation. While he may have been able to tolerate an appropriate dose of benzocaine, it was decided to try an alternative approach.

123 INDUSTRIAL POISONING: INFORMATION AND CONTROL

Peter H. Wald

Many important problems are associated with the diagnosis and treatment of occupational and environmentally caused diseases, including (1) the ability to correctly establish the diagnosis, (2) the ability to correctly treat the condition, and (3) the ability to correctly act on any public health issues related to the exposure. The following discussion instructs clinicians on how to assemble adequate information to achieve the appropriate diagnosis and treatment.

TAKING AN OCCUPATIONAL HISTORY

Because time spent at work is a large percentage of many people's day, the occupational health history should be a routine part of any medical history. This is especially true of patients who present to health care with potential xenobiotic exposures. The history should include several brief survey questions. Positive responses then lead to a more detailed occupational and environmental history, which is composed of three elements: present work, past work, and nonoccupational exposures.

The Brief Occupational Survey

The following three questions should be incorporated into the occupational survey:

Exactly what kind of work do you do?

Are you exposed to any physical (radiation, noise, extremes of temperature or pressure), chemical (liquids, fumes, vapors, dusts, or mists), or biologic hazards at work ([Table 123–1](#))?

TABLE 123–1. Hazard Classes, Hazard Types, and Several Common Examples Found in the Workplace

<i>Hazard Class</i>	<i>Hazard Type</i>	<i>Examples</i>
Physical hazards	Human–machine interfaces	Repetitive motion Lifting Vibration Mechanical trauma, electric shock
	Physical environment	Temperature Pressure Long or rotating shifts
	Energy	Ionizing radiation: x-ray, ultraviolet Nonionizing radiation: infrared, microwave, magnetic fields Lasers Noise
Chemical hazards	Solvents	Aliphatics, aromatics, alcohols, ketones, ethers, aldehydes, acetates, peroxides, halogenated compounds
	Metals	Lead, mercury, cadmium
	Gases	Combustion products, irritants, simple and chemical asphyxiants, oxygen-deficient environments
	Dusts	Organic (wood) and inorganic (asbestos or silica), nano-materials
	Pesticides	Organic chlorine, organic phosphorus, carbamate
	Epoxy resins and polymer systems	Toluene diisocyanate, phthalates
Biologic hazards	Bacteria	<i>Bacillus anthracis</i> , <i>Legionella pneumophila</i> , <i>Borrelia burgdorferi</i>
	Viruses	Hepatitis, HIV, Hantavirus
	Mycobacteria	<i>Mycobacterium tuberculosis</i>
	Rickettsia and <i>Chlamydia</i>	<i>Chlamydia psittaci</i> , <i>Coxiella burnetii</i>
	Fungi	<i>Histoplasma capsulatum</i> , <i>Coccidioides immitis</i>
	Parasites	<i>Echinococcus</i> spp, <i>Plasmodium</i> spp
	Envenomations	Arthropod, marine, snake
	Allergens	Enzymes, animals, dusts, insects, latex, plant pollen dusts

Are your symptoms related in any way to starting or being away from work? For example, do the symptoms start when you arrive at work at the beginning of the day or week or when you work at a specific location or during a specific process at work?

Present Work

Collected data on a person's present job reveal what his or her present exposures may be, which can help formulate the differential diagnosis for the employee's complaints. These data can be systematically collected by focusing on four areas: specifics of the job, hazardous exposures, health effects, monitoring, and control measures (Table 123–2).

TABLE 123–2. Components of an Occupational Health History

Current work history
 Specifics of the job
 Employer's name

Type of industry

Duration of employment

Employment location, hours, and shift changes

Description of work process

Unusual activities of the job that are occasional (eg, maintenance)

Adjacent work processes

Hazardous exposures (Table 123-1)

Possible health effects

Suspicious health problems

Temporality of symptoms

Specific distribution of symptoms (rash, paresthesias)

Affected coworkers

Presence or absence of known risk factors (smoking, alcohol)

Workplace sampling and monitoring

Individual or area air monitoring

Surface sampling Biologic monitoring

Medical surveillance records

Exposure controls

Administrative controls

Process engineering controls

Enclosure

Shielding

Ventilation

Electrical and mechanically controlled interlocks

Personal protective equipment

Respirators

Protective clothing

Earplugs, glasses, gloves, face shields, head and foot protection

Work history (prior)

Review current work history for all past employment

Nonoccupational exposures

Secondary employment

Hobbies

Outdoor activities

Residential exposures

Community contamination

Habits: tobacco, alcohol, other xenobiotics

Specifics of the Job. It is not sufficient simply to inquire what the patient does for a living. Similar to health care professionals, workers in other industries have their own jargon. When asked for a job title, a patient may respond with a title that has meaning only in his or her trade. Even if the job title is recognizable, it may not provide any useful information and, in fact, may be misleading. A secretary working in a small plastics manufacturing plant may have occupational exposures that are quite different from a secretary who works for a law firm.

The important specific information requested should include the name of the employer, type of industry, duration and location of employment, hours and shift changes, process description (including unusual occasional activities), and adjacent processes. The employer may be able to provide information about materials used at the plant. However, clinicians should always obtain the patient's permission before calling the employer. A patient may be fired or otherwise discriminated against (despite legal protections) for suggesting that health problems are work related.

It is important to learn precisely what happens in the patient's immediate work environment because nearby work processes may contribute other exposures. If possible, the patient should be asked for a diagram of the work area. The patient also should be questioned about job process changes. A previously safe job may have been changed to a potentially dangerous job without a change in the patient's job title.

The patient should describe exactly what he or she does on any given day and for how long. Unusual and nonroutine tasks, such as those performed during overtime, maintenance, or in an emergency, should also be described. The primary job may not involve xenobiotics, but the patient may nevertheless perform tasks that entail unprotected exposure to a toxic xenobiotic.

Hazardous Exposures. The names or types of all xenobiotic to which the patient may be exposed are important in determining potential adverse effects and any relationship to the patient's complaints. It is important to elicit any recent changes in suppliers of these products because even a slight change in the formulation of a xenobiotic may cause adverse effects in an individual who previously had no problems working with that xenobiotic. This information may be obtained from the material safety data sheet (MSDS), an important but not universally reliable source of information. In addition to adverse health effects, the MSDS contains information on chemical reactivity, safety precautions, and other data. As an initial step, the MSDS should be requested and reviewed; however, information provided on health effects should be confirmed using other resources. Four major concerns result from relying solely on the MSDS: (1) some MSDS forms are excellent, but others are incomplete and inadequate; (2) components of a product that are regarded as "trade secrets" do not have to be revealed; (3) components that have important health effects (eg, solvent or solid carriers of the "active ingredients") often may be grouped together under "inert ingredients" without being specifically named; and (4) process intermediates or unintended byproducts of a manufacturing process may not be identified. However, if a xenobiotic is believed to be related to a health effect, manufacturers are required to release to a physician all information, including trade secrets and inert components.

Exposures to physical and biologic xenobiotics can be elicited during the review of job processes. Most patients know what they are, or have been, exposed to, even if they do not know the exact name of the xenobiotics or its medical effects.

Health Effects. Significant occupational exposures usually cause medical effects, although some do so only after a substantial latency period. Key areas of inquiry include suspicious health problems, temporality of symptoms, and affected coworkers. These data, combined with workplace monitoring and sampling data, may help in determining whether the patient is experiencing a work-related illness ([Table 123–3](#)). Patients may suspect that their illness or complaint is work related, especially when symptoms occur at the workplace and improve or disappear over the weekend or during a vacation. Specific distribution of findings, such as a rash in a bilateral glove pattern, is supportive of an occupational cause. Coworkers with similar complaints (not necessarily of the same severity) should raise suspicion that a workplace exposure is responsible for a particular symptom complex. Diseases such as lung cancer or hepatitis, which occur in the absence of known risk factors such as smoking and alcohol, must be epidemiologically investigated

TABLE 123–3. Evidence Supporting Work-Relatedness of Occupational Disease

Known or documented exposure to a causative xenobiotic
Symptoms consistent with suspected workplace exposure
Suggestive or diagnostic physical signs
Similar problems in coworkers or workers in related occupations
Temporal relationship of complaints related to work
Confirmatory environmental or biologic monitoring data
Scientific biologic plausibility
Absence of a nonoccupational etiology
Resistance to maximum medical treatment because employee continues to be exposed at work

Workplace Sampling, Monitoring, and Control. Control of workplace hazards begins with an industrial hygiene monitoring program. Employers are required to give results of both area and individual sampling to employees. A medical surveillance program that includes periodic spirometry and respiratory questionnaires usually indicates that the patient works with a potential respiratory toxin. A medical surveillance program that includes biologic monitoring for a specific xenobiotic may also provide an immediate clue to what may be causing the patient's complaints. Finally, if the patient knows exactly what he or she is working with, the physician can usually quickly determine whether any of the xenobiotics are compatible with the patient's complaints. Many companies do not perform routine industrial hygiene monitoring or medical surveillance. Individuals who become sick or ill at work are often sent to local emergency departments. In such situations, emergency physicians may need to perform the type of time-consuming, detailed occupational history outlined here or be able to consult or refer immediately to appropriate physicians or clinics.

Portions of [Table 123–2](#) and the following section on Evaluation and Control of Workplace Hazards detail the types of controls typically used in workplaces. It is important to determine whether the workplace uses any of the following control measures; engineering controls, work practice protocols, administrative controls, or personal protective equipment. The existence of control measures usually indicates that the employer recognizes and has attempted to deal with a hazardous exposure.

Past Work

It is important not to limit the occupational history to the patient's current workplace and job. Many occupational diseases have long latency periods between xenobiotic exposure and initial development of clinical symptoms. In addition, patients may have been exposed to xenobiotics at work that make them more sensitive to other environmental xenobiotics. For example, someone who developed asthma secondary to a previous workplace exposure may have asthma attacks upon exposure to simple irritants in the current workplace. When taking an in-depth occupational history, issues that may be relevant to the current work history as well as for each previous job should be explored.

Nonoccupational Exposures

Workers may be exposed to toxic xenobiotics in the course of pursuing secondary employment, hobbies, or outdoor activities in contaminated or industrial areas. Residential exposures, such as those from gas and wood stoves, chemically treated furniture and fabrics, and pest control, may be relevant. It is important to ask patients about these potential exposures before focusing entirely on exposures in their primary place of employment. This obviously includes relevant issues from the social history, such as tobacco, alcohol, and both licit and illicit drug use.

EVALUATION AND CONTROL OF WORKPLACE HAZARDS

Initial Workplace Evaluation

The Occupational Safety and Health Act (OSHA) places legal responsibility for providing a safe and healthy workplace on the employer. The rationale for this placement of responsibility is that the employer is in the best position to make any modifications necessary to prevent additional work-related illness and injury. The physician may wish to initiate a dialogue with a patient's employer to promote preventive action but should do so only with the patient's informed consent. The initial treating physician may also refer the patient to an occupational medicine specialist, who is specifically trained to manage work-related exposures and diseases and initiate prevention programs.

Because the initial contact may influence subsequent events, it is important for the health care provider to identify an individual with an appropriate administrative role, such as someone in the company's medical department, the patient's supervisor, the plant's safety officer, or the shop manager. If management is willing to examine the hazardous conditions, a plant walk-through inspection can provide unique insight and information usually unavailable in an office setting. A walk-through by an occupational medicine specialist makes it easier to understand the work environment, identify safety and

health hazards, assess control measures, and recognize opportunities for prevention. It also facilitates a good working relationship with key personnel in management and labor. The physician, who cares for a number of patients who work in the plant or who provides health services to the workers through the company or labor union, may wish to be involved in the walk-through. Assistance with plant inspections can be obtained from occupational health specialists, such as occupational physicians or industrial hygienists.

Industrial Hygiene Sampling and Monitoring

Equipment is available to measure airborne concentrations of toxic xenobiotics, noise levels, radiation levels, temperature, and humidity. Employees can be fitted with pumps and other devices to measure individual exposure concentrations at the breathing zone, where, depending on what controls are used, concentrations may vary from those in the general work area. These results then can be compared with OSHA standards and other available standards to help determine the extent of the hazard and to formulate a control plan. OSHA requires that employers monitor the concentrations of only a few specific hazards, including arsenic, asbestos, benzene, cadmium, chromium, cotton dust, ethylene oxide, formaldehyde, lead, noise, and vinyl chloride. A complete listing of all xenobiotics is available in the OSHA standard 29 CFR 1910 Part Z—Toxic and Hazardous Substances (http://www.osha.gov/pls/oshaweb/owastand.display_standard_group?p_toc_level=1&p_part_number=1910). In addition, monitoring is required for certain operations such as hazardous waste operations or entering a confined space that may have an oxygen-deficient atmosphere. Ongoing sampling of the remaining estimated 60,000 xenobiotics used in the workplace is not required. Where industrial hygiene sampling is performed, OSHA's medical access standard gives any exposed worker or his or her representative the right to review and copy all sampling data.

Control of Workplace Exposures

Control of exposures in the workplace has traditionally relied on a hierarchy of methods to protect workers. The preferred solution is complete elimination of the exposure by substitution. When substitution is not possible, the next preferred method consists of shielding for workers to reduce their exposure. The least favored method is personal protective equipment, which requires a positive action from the worker.

Engineering Controls. Health and safety professionals prefer, and OSHA regulations require when feasible, the use of engineering controls to reduce worker exposure to hazardous xenobiotics. These controls intercept hazards at their source or in the workplace atmosphere before they reach the worker. Engineering controls include redesign or modification of process or equipment to reduce hazardous emissions; isolation of a process through enclosure; automation of an operation; and installation of exhaust systems that remove hazardous dusts, fumes, and vapors. Local exhaust systems, such as hoods, are preferable to general dilution ventilation because the former removes contaminants closer to their source and at relatively high rates.

Engineering controls have several advantages over control measures focused on the worker. Properly installed and maintained engineering controls are reliable and consistent, and their effectiveness does not depend on human supervision or interaction. They can simultaneously limit exposure through several routes, such as inhalation and skin absorption. In addition, engineering controls do not place a burden on the worker or interfere with worker comfort or safety.

Work Practices. Work practices are procedures that the worker can follow to limit exposure to hazardous xenobiotics. Examples are the use of high-powered vacuum cleaners instead of compressed air cleaning and pouring techniques that direct hazardous xenobiotics away from the worker. Although not as effective as engineering controls, work practice can be a useful component of an overall hazard control program.

Administrative Controls. Administrative controls reduce the duration of exposure for any individual worker or reduce the total number of workers exposed to a hazardous xenobiotic. Examples are rotating workers into and out of hazardous areas so that no single worker is exposed full time and scheduling procedures likely to generate high concentrations of xenobiotics, such as cleaning or maintenance activities, during nights or weekends. Administrative controls sometimes have the side effect of exposing more workers, albeit at lower doses that are hoped do not cause health effects.

Personal Protective Equipment. Personal protective equipment, such as respirators, earplugs, gloves, and hard hats, is the least effective but most commonly used control method. Personal protective equipment may be the only viable protection strategy when other controls are not practical but can also be used as an additional layer of protection in the presence of engineering controls. Some employers may favor personal protective equipment over the institution of more costly engineering and administrative controls.

Respirators and other forms of personal protective equipment often are hot, uncomfortable, and awkward to wear and may make it difficult for workers to breathe, speak, or hear, depending on the equipment involved. Consequently, workers often remove or refuse to wear the protection. Respirators place extra stress on the heart and the lungs. Both respirators and earplugs limit conversation and therefore present a safety hazard in themselves.

Because personal protective equipment does not stop a hazard from entering the environment, the worker is entirely vulnerable to exposure if the equipment fails. In addition, generally only one route of exposure is protected. For example,

the commonly used half-mask respirator still leaves the skin and eyes exposed.

Choosing the right piece of personal protective equipment can be difficult and may depend on the nature and extent of the hazard. For example, each type of respirator is rated for the amount of protection it provides; as expected, the cost of a respirator increases with its protection factor. Use of the wrong type of respirator can leave the worker insufficiently protected.

Half-mask respirator cartridges are available in various colors that are coded to the xenobiotic filtered out of the breathing environment. If the wrong cartridge is used, the worker is essentially unprotected from the hazardous contaminant. To be effective, a respirator must be meticulously fit to the individual worker. Failure to achieve a proper seal negates the respirator's usefulness. High cheekbones, dentures, scars, perspiration, talking, head movements, and facial hair can prevent a proper seal. These factors often are ignored or overlooked by an employer who adopts a "one-size-fits-all" policy.

Even if each employee is provided the proper respirator, the respiratory protection program may not be effective. OSHA requires that employers institute a program of proper fit testing, cleaning, maintenance, and storage of respirators, which can be at least as costly as the institution of engineering controls.

In some instances, use of personal protective equipment may be unavoidable. An employer may need to control a hazardous exposure through a combination of measures, such as engineering controls and personal protective equipment. Ideally, the employer is using personal protective equipment as a control of last resort and in strict compliance with OSHA standards.

Worker Education and Training. Regardless of the control measures used, workers and supervisors must be educated in the recognition and control of workplace hazards and the prevention of work-related illness and injury. The OSHA Hazard Communication Standard requires that employers train workers in ways to detect the presence or release of hazardous xenobiotics, their physical and health hazards, methods of protection against the hazards, and proper emergency procedures, as well as how to read the labeling system and how to read and use an MSDS.

With the passage of federal, state, and local right-to-know laws, many consulting companies now offer hazard communication training. These programs are of uneven quality. Those that tend to focus on acute hazards, ignore chronic effects, and that emphasize personal protective equipment over other control measures may not be effective in training workers to recognize and control hazardous xenobiotics.

Medical Monitoring. Together with industrial hygiene monitoring, exposure control, and worker education, a medical monitoring program can form the foundation of an effective occupational disease prevention regimen. However, medical monitoring is fraught with technical and ethical pitfalls. Medical monitoring encompasses both medical screening and medical surveillance.

Medical screening refers to the cross-sectional testing of a population of workers for evidence of excessive exposure or early stages of disease that may or may not be related to work and that may or may not influence the ability to tolerate or perform work.

Preemployment and preplacement physical examinations are another type of medical screening that are often favored by employers. The Americans with Disabilities Act (ADA) and the newer ADA Amendment Act of 2008 (ADAAA) regulate the timing, scope, content, and use of these examinations and the information gathered. Comprehensive resources for information on the ADA are available at <http://www.adata.org>. The ADA prohibits "preemployment" medical examinations and inquiries. After a job offer has been made, "preplacement" examinations and inquiries can be conducted to determine whether an applicant can perform a job safely and effectively. The physician evaluates the individual's medical history, current symptoms, and physical laboratory findings to determine whether he or she currently has the physical or mental abilities necessary to perform the essential functions of the job, and whether the individual can do so without posing a "direct threat" to the health or safety of him- or herself or others. This threat must be more than theoretical and cannot be based on some future time; the threat must be concrete and relatively immediate.

Few tests and few conditions are good predictors of either the ability to perform a task or increased susceptibility to a particular exposure. Many workers and their advocates view preplacement examinations as a way for employers to choose the "fittest" worker and to avoid their legally mandated obligation to provide a safe and healthy workplace for all workers. This is not true for most employers. Physicians asked by an employer to perform preplacement examinations should be sure that each component of the examination relates to the actual job the individual is being hired to perform and the actual risks he or she will encounter on the job. Both the law and sound occupational medical practice dictate that the employer's attention and efforts be directed toward redesign of the job and its hazards so that it is safe and healthy for all workers to perform.

Medical surveillance refers to the ongoing evaluation, by means of periodic examinations, of high-risk individuals or potentially exposed workers to detect early pathophysiologic changes indicative of significant exposure. OSHA requires little in the way of medical surveillance, although several OSHA standards require employers to institute medical surveillance programs, for example, for workers exposed to asbestos, arsenic, cadmium, chromium, vinyl chloride, lead, and ethylene oxide. Depending on the potential exposure, medical surveillance may include a history and physical examination, chest radiography, pulmonary function tests, blood and urine tests, and other laboratory evaluations.

A medical surveillance program may also include biologic monitoring, the purpose of which is not to identify the occurrence of disease but to measure the uptake or presence of a particular xenobiotic or its metabolites in body fluids or organs. Ideally, this occurs before any pathophysiologic damage occurs. Consequently, biologic monitoring is potentially a primary preventive measure. For example, several volatile organic compounds, such as benzene and toluene, if inhaled or absorbed through the skin, produce metabolites that can be measured in urine.

Biologic monitoring can have some advantages over air monitoring because biologic monitoring measures the actual absorption of a xenobiotic by the body as opposed to ambient concentrations in the workplace. The amount of a chemical absorbed may not be closely correlated to ambient xenobiotics for several reasons, including differences in individual work habits, use and effectiveness of personal protective equipment, dermal absorption of xenobiotics unrelated to their concentration in the air, and nonoccupational exposures.

Biologic monitoring, however, has several significant limitations. For most xenobiotics, there are no standards of “normal” or “safe” concentrations against which results can be compared. The timing of specimen collection is critical because different xenobiotics have different biologic half-lives. The storage and handling of specimens and interpretation of results are vulnerable to error. Nevertheless, if carefully designed and implemented, biologic monitoring can be a useful complement to a comprehensive industrial hygiene program.

With the exception of biologic monitoring, medical monitoring programs identify disease processes already underway and therefore are, at best, a form of secondary prevention. If workers are identified as having higher than acceptable exposures, they should be removed from exposure with continuing pay while their concentrations decline, and while the employer investigates any potential breakdown in the workplace controls. To be an effective preventive measure, these programs must be coordinated with environmental monitoring programs that identify the nature, source, and extent of workplace hazards; implementation of engineering controls and other measures that control hazards as close as possible to the source; and worker education programs that, at a minimum, inform workers of exposures, their effects, and proper control measures.

Both medical monitoring programs and preplacement examinations raise issues of doctor–patient confidentiality. Employee medical records should be available only to the corporate medical or first aid department and not to the personnel office and general management. Unless required by statute, employers should never be told the results of history, physical, or diagnostic examinations unless the patient gives his or her written consent. The examining physician need only inform the employer that an individual is or is not capable of performing a particular job with or without specified restrictions. The physician should not disclose diagnostic information about medical conditions.

INFORMATION RESOURCES

Health care professionals require information on industrial toxins in a number of situations, ranging from caring for an acutely ill patient in an emergency department, when information must be obtained quickly, to caring for a patient with chronic symptoms that may reflect an occupational disease. However, the use of information resources depends on the proper identification of the xenobiotic in question. If the xenobiotic, its generic name, and ingredients are not known, the research process becomes more difficult.

The practitioner should take a logical approach to seeking information about industrial xenobiotics. First, the xenobiotic must be identified by its generic name. This can be done by reviewing the MSDS or by contacting poison centers (PCs), the employer, manufacturer, unions, or government agencies. MSDSs also are available by searching online. A good starting point to find MSDSs on the Internet is <http://www.ilpi.com/MSDS/index.html>, but typing “MSDS” into any online search engine yields a number of sites offering data sheets.

Poison Centers

Regional PCs can provide assistance even when the exact chemical name is unknown because information on xenobiotics and their management may be cross-referenced by trade name and manufacturer. Moreover, Specialists in Poison Information can usually suggest additional resources. Most PCs have computerized listings of poisons that are updated regularly. The best-known system is POISINDEX (Truven Health Analytics, Ann Arbor, MI). Subscribers to this system receive quarterly updates of an alphabetically organized listing of approximately 500,000 industrial and nonindustrial xenobiotics. The system includes trade names, the components, and the concentrations, when available, of each xenobiotic listed. These elements are then cross-referenced to management protocols. The name of the manufacturer is also listed.

Employers and Manufacturers

Many state and federal laws require manufacturers to generate, retain, and disclose information that may help physicians care for persons with work-related health problems. Scientific information, exposure data, information on health effects, and collected medical data are included in the types of information that must be retained.

The Chemical Transportation Emergency Center (CHEMTREC; 800-424-9300; <http://www.chemtrec.com>), sponsored

by the Chemical Manufacturers Association, has as its primary responsibility providing information to health care practitioners responding to hazardous spills. However, it also provides information on commercial products found in patients’ workplaces. Employers are required to furnish this information to employees in the form of MSDSs.

Worker’s Compensation Insurance Carriers

Smaller companies often lack internal health and safety staffs. Worker’s compensation or company risk insurance carriers may have valuable information about exposures and controls in the workplace. As a service to their clients, carriers often do walk-throughs and hazards evaluations for clients that lack these resources and suggest appropriate engineering controls. Health care professionals can contact the carrier directly to see what additional information is available.

Regulatory Agencies

OSHA requires chemical manufacturers to create an MSDS for each chemical they produce, and employers who use chemicals must retain the MSDSs in the workplace. Required information includes xenobiotic and common names; physical, safety, and health hazard data; exposure limits; precautions for safe handling and use; generally applicable control measures; and emergency and first aid procedures. The OSHA Hazardous Communication Standard requires individual employers to provide employees with information on the xenobiotics used in their workplaces. With the patient’s permission, a call to the plant manager, foreperson, or safety officer may be all that is necessary to determine the name of the xenobiotic in question. Employers may be able to provide information on exposure concentrations in the patient’s work environment. In addition, company medical departments (where they exist) may have results of medical testing done on the patient.

There is an important point to reiterate about MSDSs: health care providers should not rely on these sheets as the sole source of information. The MSDSs are created by the chemical manufacturers as they generate scientific and health data during the course of seeking approval from the Environmental Protection Agency (EPA) to manufacture xenobiotics, and they are not a complete product evaluation. In addition, Section 8(c) of the Toxic Substances Control Act (TSCA) requires chemical manufacturers to report records of significant adverse reactions to human health or the environment. When contacting chemical manufacturers, physicians should ask to speak with a toxicologist, chemist, or someone in the products information department.

Unions

Labor unions can be excellent sources of information on xenobiotic exposures. At the local level, union officers, health and safety committee members, and shop stewards may be able to provide MSDSs, exposure data, medical and epidemiologic information, and reports of incidents or cases of interest in a particular plant. The health and safety department of the American Federation of Labor and Congress of Industrial Organizations (AFL-CIO), (<http://www.aflcio.org/Issues/Job-Safety>) in Washington, DC, can provide information on occupational health and safety activities and advice on which member unions may be of specific help. At the international level, unions often have well-trained health and safety professionals who may provide or suggest sources of helpful information (<http://www.ilo.org/global/topics/safety-and-health-at-work/lang—de/index.htm>). In addition, some cities and states (<http://www.nycosh.org/>) have a coalition of occupational safety and health groups that may provide information about other known exposed or affected workers.

Government Agencies

A myriad of agencies have some regulatory authority over manufacturing and services industries. These agencies and their important regulatory authority are listed in [Table 123–4](#).

TABLE 123–4. Government Agencies and Their Important Regulatory Authority of the Workplace—A Timeline

Regulation	Agency	Authority
Occupational Safety and Health Act (OSHA, 1970)	Department of Labor	<p>Congress passed OSHA and created the Occupational Safety and Health Administration to ensure worker and workplace safety. The goal was to make sure employers provide their workers a place of employment free from recognized hazards to safety and health, such as exposure to toxic xenobiotics, excessive noise levels, mechanical dangers, heat or cold stress, and unsanitary conditions.</p> <p>To establish standards for workplace health and safety, the Act also created the National Institute for Occupational Safety and Health (NIOSH) as the research institution for the Occupational Safety and Health Administration. Part 1910.1200 of OSHA established the Hazardous Communication Standard (HazCom). The purpose of this section is to ensure that the hazards of all xenobiotics produced or imported are evaluated and that information concerning their hazards is transmitted to employers and employees. This transmittal of information is to be accomplished by means of comprehensive hazard communication programs, which are to include container labeling and other forms of warning, material safety data sheets, and employee training.</p>
Resource Conservation and Recovery Act (RCRA, 1976)	Environmental Protection Agency (EPA)	<p>RCRA (pronounced "rick-rah") gave the EPA the authority to control hazardous waste from "cradle to grave." This includes the generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of nonhazardous wastes. The 1986 amendments to RCRA enabled the EPA to address environmental problems that could result from underground tanks storing petroleum and other hazardous xenobiotics. RCRA focuses only on active and future facilities and does not address abandoned or historic sites (see CERCLA).</p> <p>HSWA (pronounced "hiss-wa"), the Federal Hazardous and Solid Waste Amendments, are the 1984 amendments to RCRA that required the phasing out of land disposal of hazardous waste. Some of the other mandates of this strict law include increased enforcement authority for the EPA, more stringent hazardous waste management standards, and a comprehensive underground storage tank program.</p>
Toxic Substances Control Act (TSCA, 1976)	EPA	<p>TSCA was enacted by Congress to give the EPA the ability to track the 75,000 industrial xenobiotics currently produced or imported into the United States. The EPA repeatedly screens these xenobiotics and can require reporting or testing of those that may pose an environmental or human health hazard. The EPA can ban the manufacture and import of xenobiotics that pose an unreasonable risk.</p> <p>Reporting requirements include (1) premanufacturing notification for new xenobiotics, (2) allegation of significant adverse reactions, (3) reporting of health and safety studies, and (4) notification of suspicion of substantial risk to health.</p>
Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, 1980)	EPA	<p>CERCLA, commonly known as the Superfund Act, was enacted by Congress on December 11, 1980. This law created a tax on the chemical and petroleum industries and provided broad federal authority to respond directly to releases or threatened releases of hazardous xenobiotics that may endanger public health or the environment. Over 5 years, \$1.6 billion was collected, and the tax went to a trust fund for cleaning up abandoned or uncontrolled hazardous waste sites. CERCLA (1) established prohibitions and requirements concerning closed and abandoned hazardous waste sites, (2) provided for liability of persons responsible for releases of hazardous waste at these sites, and (3) established a trust fund to provide for cleanup when no responsible party could be identified.</p> <p>The law authorizes two types of response actions: (1) short-term removals, in which actions may be taken to address releases or threatened releases requiring prompt response, and (2) long-term remedial response actions that permanently and significantly reduce the dangers associated with releases or threats of releases of hazardous xenobiotics that are serious but not immediately life threatening. These actions can be conducted only at sites listed on the EPA's National Priorities List (NPL).</p>
Superfund Amendments and Reauthorization Act (SARA, 1986)	EPA	<p>SARA reflected the EPA's experience in administering the complex Superfund program during its first 6 years and made several important changes and additions to the program. SARA (1) stressed the importance of permanent remedies and innovative treatment technologies in cleaning up hazardous waste sites, (2) required Superfund actions to consider the standards and requirements found in other state and federal environmental laws and regulations, (3) provided new enforcement authorities and settlement tools, (4) increased state involvement in every phase of the Superfund, (5) increased the focus on human health problems posed by hazardous waste sites, (6) encouraged greater citizen participation in making decisions on how sites should be cleaned up, and (7) increased the size of the trust fund to \$8.5 billion. SARA also required the EPA to revise the Hazard Ranking System (HRS) to ensure that it accurately assessed the relative degree of risk to human health and the environment posed by uncontrolled hazardous waste sites that may be placed on the NPL. Emergency Planning and Community Right-to-Know Act (EPCRA), also known as Title III of SARA, was enacted by Congress as the national legislation on community safety. This law was designated to help local communities protect public health, safety, and the environment from xenobiotic hazards. The law requires manufacturers to report the amount of toxic xenobiotics released each year (Toxic Release Inventory [TRI]).</p> <p>To implement EPCRA, Congress required each state to appoint a State Emergency Response Commission (SERC). The SERCs were required to divide their states into Emergency Planning Districts and to name a Local Emergency Planning Committee (LEPC) for each district.</p>
Americans with Disabilities Act (ADA, 1990) and the ADA Amendments Act of 2008 (ADAAA)	Department of Labor	<p>The ADA was enacted by Congress to establish clear and comprehensive prohibition of discrimination on the basis of disability. The act specifically covers discrimination in the areas of (1) employment, (2) public services, (3) public accommodations and services operated by private entities, and (4) telecommunications. The ADAAA reaffirms Congress' initial intent of the 1990 law to (1) broadly define "disability," (2) use the definition of "handicapped individual" under the Rehabilitation Act of 1973 and (3) state that mitigating measures (eg, insulin for diabetes) shall not be a factor when determining whether an impairment substantially limits a major life activity. The final regulations for the Act were published in the Federal Register in March 2011. http://www.eeoc.gov/laws/regulations/adaaa_fact_sheet.cfm.</p>

OSHA of the U.S. Department of Labor (<http://www.osha.gov>) is responsible for setting and enforcing workplace health and safety standards. It is empowered to investigate occupational health and safety complaints and can inspect work sites and levy fines for violations of its standards. In approximately half of the 50 states, the OSHA program is implemented by a state agency. Individual workers, their representatives (unions), or their physicians can file a complaint with the state or federal OSHA program and request an inspection. OSHA regulations protect workers from discrimination and punishment by their employer, who may be angered by their filing a complaint.

Some state OSHA agencies have separate enforcement and consultation arms. Thus, companies can request assistance from the occupational health specialists in the consultation branch without fear of reprisal from the enforcement branch. Health care workers should be familiar with the functions of their state agency and workers' rights under the law.

The National Institute for Occupational Safety and Health (NIOSH) of the U.S. Department of Health and Human Services is part of the Centers for Disease Control and Prevention (<http://www.cdc.gov/niosh>). NIOSH is not a regulatory agency and is responsible for researching the causes of occupational disease and injury and methods for their prevention and control, evaluating workplace conditions, recommending exposure limits to OSHA for standard setting, and training occupational health and safety professionals. It is empowered to conduct onsite evaluations of health hazards in response to requests from employee representatives or employers. After conducting these evaluations, NIOSH investigators immediately contact OSHA, the employees, and the employer if they find that the workers are in imminent danger.

As part of the process of recommending exposure standards to OSHA, NIOSH develops comprehensive documents that critically evaluate all available scientific data on particular xenobiotics. These “criteria documents” review the chemical’s properties, production methods, uses, and workers at risk as well as studies of exposure effects in humans and animals. Methods of screening, surveillance, and control are presented. The agency periodically issues technical reports and special occupational hazard reviews of specific occupations. In conjunction with OSHA, NIOSH develops and disseminates health hazard alerts to inform employers, employees, and health care professionals of serious health effects of particular xenobiotics.

The EPA (<http://www.epa.gov>) is charged with protecting the nation’s land, air, and water. The agency administers a number of laws designed to preserve the public health and environment, one of which is the Toxic Substances Control Act (TSCA). This act authorizes the EPA to collect information on xenobiotic risks from manufacturers and processors and to review information on new xenobiotics and new uses of xenobiotics before they are manufactured. Unless designated a trade secret, this information is subject to disclosure and therefore is available. The TSCA assistance office may be most useful when resource materials and government documents contain no information about the xenobiotics or processes in question.

The National Toxicology Program (NTP; <http://ntp.niehs.nih.gov/>) is a federal program established in 1978 to develop scientific information on exposure to xenobiotics.

The Agency for Toxic Substances and Disease Registry (ATSDR; <http://www.atsdr.cdc.gov>) was created by Congress in the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERLA; also known as Superfund Act) to implement the health-related sections of laws that protect the public from hazardous wastes and environmental spills of hazardous substances. In 1986, the Superfund Amendments and Reauthorization Act (SARA) made amendments to the initial enabling legislation of 1980 and broadened the ATSDR’s responsibilities in the areas of health assessment, toxicologic databases, information dissemination, and medical education. One of its offices, the Division of Health Assessment and Consultation, provides emergency response for toxic and environmental disasters, consults in public health emergencies, assesses hazardous waste sites, provides technical assistance to agencies and organizations, and estimates health risks to humans from exposure to hazardous xenobiotics. The program areas in which ATSDR operates include health assessments, toxicologic profiles, emergency response, and exposure and disease registries.

Online Databases

Printed material often is adequate for determining the adverse health effects of xenobiotic exposures, but some resources may be unavailable to physicians, and textbook publications usually lag 2 years or more behind new information. As a result, current findings and reports may be missed if the practitioner relies solely on printed material. The National Library of Medicine (<http://www.nlm.nih.gov>) now sponsors Internet searching of both Medline (PubMed: <http://www.ncbi.nlm.nih.gov/pubmed>) and a number of databases in the Toxicology Data Network (TOXNET: <http://www.toxnet.nlm.nih.gov>) that are very useful for finding information about industrial xenobiotics. Additional databases are available for searching on the OSHA, NIOSH, EPA, and ATSDR web sites.

Obligations of the Health Care Provider to the Individual Patient, Coworkers, Employer, Government, and Community

Occupational diseases and injuries are, in principle, preventable. Physicians who diagnose a work-related disease or injury have an opportunity and an ethical obligation to participate in the identification and control of workplace hazards and the prevention of further occupational illness and injury. Physicians can choose from a range of possible follow-up measures, the goals of which are to prevent recurrence or worsening of the disease or injury in the patient and to prevent the development of disease or injury in other potentially exposed workers. Some of these activities may necessitate contact with occupational medicine physicians, toxicologists, industrial hygienists, lawyers, journalists, government officials, management personnel, and union officials.

Obligations to the Patient

Inform the Patient That the Illness May Be Work Related. When the workplace is determined to be a factor in the etiology or aggravation of the patient’s illness, this fact and its implications should be discussed with the patient. It should never be assumed that the patient is fully aware of the health risks associated with any workplace exposure. The worker

should be provided information regarding the nature of workplace hazards, their health risks, preventive measures, and recommendations regarding continued exposure.

Suggest How the Patient Can Reduce the Exposure. In some cases, the patient can take steps to reduce exposure. Adjustments in work habits that may be helpful include using a respirator or other personal protective equipment provided by the employer; using workplace shower and dressing rooms to avoid carrying xenobiotics from the workplace to the home; and avoiding ingestion of workplace xenobiotics by careful hand washing before eating or smoking and by taking lunch, coffee, and smoking breaks away from the work station. Obviously, these recommendations assume that the employer provides the appropriate equipment and facilities, which is not always the case. The most effective hazard control measures require significant commitment by, and cooperation from, the employer.

Suggest That the Patient Remove Him-or Herself from the Exposure. The employer may be willing to transfer the patient to a location away from the offending hazard. This may result in a reduction in pay, seniority, or other benefits, which may be compensable under workers' compensation. The employment provisions of the ADA require employers to make "reasonable accommodations" for both work-and non-work-related disabilities. Nevertheless, the employer may not be able to accommodate the patient. The patient should be counseled carefully, and other options should be explored.

Advise the Patient to Notify the Employer. Patients who are experiencing a work-related illness may be entitled to workers' compensation benefits, Social Security disability, or other government-sponsored benefit programs. In addition, they may have a valid claim against the manufacturer of a xenobiotic, a defective product, or another third party. The degree of disability necessary to bring a successful claim varies.

After a patient is informed that he or she has a work-related illness, strict time limits are set in motion, and failure to meet them can preclude the patient from successfully filing a claim or receiving needed benefits. The patient should be advised to provide written notice immediately to his or her employer of a work-related illness (supported by a physician's letter) and to seek advice about statutes of limitations and other requirements. This information is generally available from the State Workers' Compensation Board and is usually required to be provided to the employee by the employer. If a union is available at the workplace, it may be able to advise and assist the patient.

Obligations to Coworkers A patient with a work-related illness should be advised to inform his or her coworkers about the condition. If the patient belongs to a union, he or she should inform the union representative. If there is no union, the patient may contact OSHA or discuss the situation with the employer.

If the patient is a union member and agrees, the physician can contact the union, which may assist in hazard investigation, identify and warn other workers potentially affected by the hazard, and pressure the employer to take corrective action if it is unwilling to do so. The union can help the patient obtain any available benefits. The patient may be able to identify appropriate contacts, such as shop stewards, members of the union's health and safety or workers' compensation committees, an occupational health specialist employed by the union at the local or national level, or an official of the union local.

Committees on Occupational Safety and Health (COSH); coalitions of labor, health, and legal professionals; and community and environmental activists working to prevent job-related illness and injury may be able to help with the diagnosis and follow-up of occupational diseases. These groups provide education and technical assistance nationwide on a range of topics, including the health effects of specific hazards, control measures, how to use government agencies, and the legal rights of disabled workers.

Obligations to Notify the Government

States may have laws that require direct physician reporting of occupational disease. If management is uncooperative despite notification of a hazardous situation, OSHA should be contacted, with the patient's consent. In addition to the federal agencies specifically empowered to protect worker health and safety, physicians may contact the state or local health department, which may initiate action or refer the problem to one of the federal agencies. Many states also require physicians to report any occupational injury or illness to the workers' compensation carrier.

Obligation to Notify the Employer

When treating a patient with an occupational injury or illness, health care providers often are required to report to government agencies, health departments, or insurance carriers. As part of that reporting process, the employer should also be notified. When there is imminent danger to coworkers or the public health, the employer should be contacted to correct the exposure situation.

Obligation to Inform Colleagues and the Public

On occasion, an individual primary care physician or specialist is the first person to suspect a link between a workplace exposure and a serious health problem. This is likely to recur in the future, especially if the physician practices in a small town or industrial area or provides health care to worker groups through a company or union. Armed with an increased index of suspicion and the occupational history, the physician may be able to alert workers and companies and prevent the

occurrence of a major health problem. Even if the physician chooses not to be involved in subsequent investigation or research, it is important that information about suspected problems and hazards be made available to workers and employers in similar industrial settings, government agencies, health care professionals, and perhaps the public at large. Case reports discussed in the medical literature, at medical meetings, or through the media can be helpful in this regard.

SUMMARY

- Industrial, workplace, and environmental exposures represent a different kind of challenge to primary care and emergency physicians.
- Patients often present as a diagnostic dilemma or with common symptoms that do not respond to the usual medical treatment. The challenge for nonoccupational health professionals is to correctly establish and treat the condition.
- The basic approach to all patients emphasizes additional questions integrated into the medical history and access to printed and electronic information resources.
- Exposures to occupational and environmental xenobiotics have public health implications.
- Physicians who make the diagnosis of an occupationally or environmentally related disease have an obligation to prevent further injury.

124 SIMPLE ASPHYXIANTS AND PULMONARY IRRITANTS

Lewis S. Nelson and Oladapo A. Odujebe

The respiratory system is responsible for gas exchange, elimination of certain xenobiotics, insensible water loss, temperature regulation, and minor metabolic processes. The principle function of the respiratory system is gas exchange, which occurs in the greater than 300 million alveoli that make up approximately 90% of the human lung volume. The average resting adult inhales about 8 L/min of air (a tidal volume of about 500 mL) and averages 16 breaths/min, and this volume can be increased exponentially by increasing the respiratory rate and tidal volume as occurs during exertion. In a 24-hour period, an average adult human at rest will have been exposed to 11,500 L of air. There are a number of protective systems within the respiratory system to prevent exposure to xenobiotics, but these systems can be overwhelmed. The principles of respiratory system function are covered extensively in [Chap. 29](#).

The respiratory tract performs several important physiologic functions. Its most important role involves the transfer of oxygen to hemoglobin across the pulmonary endothelium. This transfer facilitates oxygen distribution throughout the body to permit effective cellular respiration. Diverse xenobiotics may act at unique points in this distribution pathway to limit or impair tissue oxygenation. For example, whereas opioids and neuromuscular blockers may induce hypoventilation, carbon monoxide and methemoglobin inducers prevent loading and unloading of oxygen onto and off of hemoglobin. Certain xenobiotics prevent adequate oxygenation of hemoglobin at the level of pulmonary gas exchange. Two mechanistically distinct groups of xenobiotics are capable of interfering with gas exchange: simple asphyxiants and pulmonary irritants. Impairment of transpulmonary oxygen diffusion, regardless of the etiology, reduces the oxygen content of the blood and may result in tissue hypoxia.

HISTORY AND EPIDEMIOLOGY

Unlike most xenobiotic exposures, simple asphyxiant and pulmonary irritant poisonings frequently occur on a mass scale because of the nature of the inhalational route. For example, the large-scale emission of carbon dioxide from Lake Nyos, a carbonated volcanic crater lake in Cameroon, West Africa, resulted in nearly 2000 human deaths and many more livestock deaths ([Chap. 2](#)).¹⁷ In this disaster, simple asphyxiation was likely because medical evaluation of both survivors and fatalities demonstrated neither signs of cutaneous or pulmonary irritation nor toxicologic abnormalities.²⁰⁶ The widespread use of compressed liquefied gases, which expands several hundredfold on depressurization or warming, account for a substantial number of workplace injuries.^{128,188}

Irritant gases similarly may result in mass casualties. For this reason, chlorine and phosgene were used in battle during World War I, resulting in thousands of Allied deaths ([Chap. 132](#)).⁸⁷ Atmospheric sulfur dioxide and oxides of nitrogen are the primary components of photochemical smog. During the London Fog incident in 1952, 4000 deaths occurred primarily from respiratory causes.¹⁷⁶ Similar smog incidents have occurred across the globe. Relatedly, the diverse irritants found in fire smoke are a major cause of death after smoke inhalation.¹⁸⁵

Unexpected release of other irritant inhalants may lead to large-scale poisoning. In 1984, an inadvertent release of methylisocyanate in Bhopal, India, resulted in immediate and persistent respiratory symptoms in approximately 200,000 local inhabitants, with approximately 2500 deaths.^{18,57}

Isolated exposures to individuals occur as well, often in workplaces, and more frequently in contained spaces (eg, indoors). Additionally, the use of simple asphyxiation as a painless and relatively undetectable method for committing suicide and, paradoxically, for euphoric experiences, can be found in books, on the Internet, and in the medical literature.^{71,79,81,167}

SIMPLE ASPHYXIANTS

Simple asphyxiants work primarily by displacing oxygen from ambient air, unlike chemical asphyxiants, which cause cellular hypoxia and are discussed in [Chaps. 125, 126, and 127](#). Virtually every gas, excluding oxygen, is capable of acting

as a simple asphyxiant.

Pathophysiology

Simple asphyxiants displace oxygen from ambient air, thereby reducing the fraction of inspired oxygen (FiO_2) in air to below 21%, and result in a decrease in the partial pressure of oxygen. The partial pressure is a measure of the contribution of oxygen to the total inspired air and is based on both FiO_2 and barometric pressure. For example, because the ambient pressure at sea level (less water vapor, 47 mm Hg) is 713 mm Hg and the percentage of oxygen is 21%, the partial pressure of oxygen in the lungs is 150 mm Hg. However, this relationship is not applicable at other barometric pressures. For example, at the summit of a mountain, the reduced barometric pressure results in a decrease in the partial pressure of oxygen despite a near-normal FiO_2 . The barometric pressure decreases in a linear fashion with altitude (above sea level) and increases with descent below sea level. This reduced partial pressure may be insufficient to allow adequate oxygen saturation, and supplemental oxygen becomes necessary. As barometric pressure decreases, exposure to simple asphyxiant gases may further reduce the oxygen partial pressure to life-threatening levels. Conversely, underwater divers reduce their FiO_2 to below 21% by adding simple asphyxiant gases, such as helium, to their breathing mixture to avoid oxygen toxicity, yet they still maintain adequate oxygenation. This is because the elevated barometric pressure increases the partial pressure of oxygen to normal amounts despite the addition of an asphyxiant gas. However, systemically poisonous gases that enter the breathing mixture would have a magnified effect, given their increased partial pressure at depth.

Conceptually, simple asphyxiants have no pharmacologic activity. For this reason, exceedingly high ambient concentrations of these gases are necessary to produce asphyxia. Asphyxiation typically occurs in confined spaces or with rapid release of concentrated simple asphyxiants.

Clinical Manifestations

A patient exposed to any simple asphyxiant gas will develop characteristic clinical findings of hypoxia, or lack of oxygen at the cellular level (Table 124–1). These clinical findings are directly related to the reduction in the partial pressure of oxygen in ambient air, which leads to hypoxemia, or low oxygen content of the blood.¹²⁸ Cardiovascular and central nervous system (CNS) complications of simple asphyxiants predominate because these organs have the greatest oxygen requirements. As hypoxemia becomes severe, multisystem organ failure and death from tissue hypoxia may occur.⁵³ Postmortem findings are generally minimal, hampering the cause of death determination without historical evidence or advanced laboratory testing.¹²

TABLE 124–1. Clinical Findings Associated with Reduction of Inspired Oxygen

FiO_2^a	Signs and Symptoms
21	None
16–12	Tachypnea, hyperpnea, (resultant hypocapnia), tachycardia, reduced attention and alertness, euphoria, headache, mild incoordination
14–10	Altered judgment, incoordination, muscular fatigue, cyanosis
10–6	Nausea, vomiting, lethargy, air hunger, severe incoordination, coma
<6	Gasping respiration, seizure, coma, death

^aAt sea level, barometric pressure; appropriate adjustments must be made for altitude and depth exposures.

FiO_2 = fraction of inspired oxygen.

During simple asphyxiation, carbon dioxide exchange is not impaired, and hypercapnia does not occur. Because dyspnea develops more rapidly from hypercapnia than hypoxemia, the breathlessness associated with physical or simple chemical asphyxiation does not develop until severe hypoxemia intervenes.^{96,116} In these circumstances, victims may succumb to hypoxemia without ever developing the expected warning symptoms. In the case of carbon dioxide inhalation, hypercapnia may occur very rapidly, which itself may produce acute cognitive impairment.

Specific Xenobiotics

Noble Gases: Helium, Neon, Argon, and Xenon. Noble gases, which are stored almost exclusively in the compressed form, have numerous industrial and medical roles. Argon is predominantly used as a shielding gas during welding

operations, and it is also used in processing titanium and growing crystals. Neon is used in the manufacture of decorative lighting. Xenon, in its radioactive gaseous form, has diagnostic medical applications in ventilation-perfusion scans. Xenon is also used in lighting, solar simulators, digital projectors, and plasma display cells (along with neon). Helium has the lowest molecular weight and is the smallest member of the noble gas family of elements. Because of its lower lipid solubility, helium is used by divers to replace nitrogen to prevent nitrogen narcosis at depth (see Nitrogen). Even at diving gas mixtures of 50% helium, divers suffer no adverse effects as long as a normal partial pressure of oxygen is maintained by the mixture at depth. At depth, the quantity (molar quantity, not volume) of air inspired per breath is several-fold greater than at sea level. The lower density of helium than nitrogen results in a lower viscosity, with a marked decrease in flow resistance. This property of helium is the basis for its use in patients with increased airway resistance (Heliox mixture), such as those with asthma.

Helium is also used in magnetic resonance imaging scanners to keep the coils super cooled. During emergency shutdown of a superconducting electromagnet, an operation known as “quenching,” the liquid helium is rapidly boiled from the device and vented into the scanner room. This may displace oxygen from the environment and cause asphyxia.⁹⁰ Helium is also used in lung imaging studies and pulmonary function testing. Similarly, helium’s low viscosity has led to its use as an inflation gas for intraaortic balloons, for which rapid inflation and deflation are critical.

All noble gases, when compressed, form cryogenic liquids, which expand rapidly to their gas phase on decompression. Liberation of these gases in closed spaces may result in either asphyxiation or freezing injuries, or both.⁹⁰ Xenon, unlike the other noble gases, has unique anesthetic properties because of its high lipid solubility and inhibition of N-methyl-D-aspartic acid (NMDA) receptors.⁹⁰ The other noble gases have no known direct toxicity.

Short-Chain Aliphatic Hydrocarbon Gases: Methane, Ethane, Propane, and Butane. The short-chain aliphatic hydrocarbon gases are primarily used in the compressed form as fuel.

Methane (CH_4) has no known direct toxicity. Animals can breathe a mixture of 80% methane and 20% oxygen without manifesting hypoxic symptoms because their FiO_2 , and thus their oxygen content, essentially is normal. Methane, also known as “natural gas” and “swamp gas,” may be present in high ambient concentrations in bogs of decaying organic matter. In addition, compressed natural gas is now used as an alternative fuel for automotive use. Methane exposure is an occupational hazard for miners who historically carried canaries into their workplace as an “early warning” sign for the presence of toxic gases and/or oxygen deficiency. Theoretically, the higher metabolic and respiratory rates of small animals (and children) make them more rapidly susceptible to gas exposures. Methane is also an explosive risk.

Methane is odorless and undetectable without sophisticated equipment.³⁶ For this reason, natural gas is intentionally adulterated with a small concentration of ethyl mercaptan, a stenching agent, which is responsible for the well recognized sulfur odor of natural gas. Cooking with natural gas may cause respiratory symptoms and pulmonary dysfunction.⁹⁹ However, methane itself is unlikely to be the cause, because its combustion is generally complete and ambient concentrations are negligible. It is likely that exposure to nitrogen dioxide (NO_2), one of the products of combustion of methane in air (70% nitrogen), is the explanation for these symptoms.

Ethane (C_2H_6) is an odorless gas that is a component of natural gas and is used as a refrigerant. It has characteristics similar to methane and is occasionally implicated as a simple asphyxiant. Propane (C_3H_8) is widely used in its compressed, liquefied form both as an industrial and domestic fuel, and as an industrial solvent. Butane (C_4H_{10}) is a common fuel and solvent. Deliberate butane inhalation from cigarette lighters or air fresheners for recreational purposes predominantly in adolescents is associated with cardiovascular dysfunction and cerebral damage (**Chap. 84**).^{63,183}

Carbon Dioxide (CO_2). Although not a simple asphyxiant gas by definition because it produces physiologic effects, carbon dioxide closely resembles simple asphyxiants from a toxicologic viewpoint. Carbon dioxide gas has many practical industrial uses, such as production of carbonation in soft drinks and use as a shielding gas during welding. It is used in laboratories as a painless form of animal euthanasia and as a means of large-scale euthanasia of diseased livestock.¹⁵⁶ Carbon dioxide is widely used to extinguish fires because of its ability to safely displace oxygen from the local environment.⁷⁸ Dry ice, the frozen form of carbon dioxide, is an extremely cold substance (-141.3°F $\{-78.5^\circ\text{C}\}$) that undergoes conversion from solid to gas without liquefaction, a process known as sublimation. Poisoning may occur when dry ice is allowed to sublimate in a closed space.³⁹ such as the cabin of a car or in a cold storage room at 39.2°F (4°C).^{78,61} Furthermore, inadvertent connection of respirable gas hoses to carbon dioxide and other nonrespirable sources has occurred in both industrial^{96,189} and medical¹⁰⁰ settings, with resultant worker and patient fatalities. This occurrence is uncommon because of the mandated use of engineering controls to prevent the incorrect connection of hose and source terminals.

Pharmacology and pathophysiology. Carbon dioxide, an end product of normal human metabolism, dissolves in the plasma and is in equilibrium with carbonic acid (H_2CO_3). The pH at the central chemoreceptors, reflective of the dissolved carbon dioxide (PCO_2), is responsible for our respiratory drive, and PCO_2 is tightly controlled by the CNS through regulation of breathing.¹¹⁶ For this reason, exogenous carbon dioxide, combined with oxygen, was at one time used

medically as a respiratory stimulant in neonates. Under normal conditions, ambient air contains approximately 0.03% CO₂. When ambient concentrations increase, uptake of carbon dioxide occurs, which further stimulates respiration,¹⁵³ increasing the uptake of ambient carbon dioxide. Accordingly, closed anesthesia systems use scrubbers containing sodium hydroxide (NaOH) to chemically eliminate exhaled carbon dioxide. Failure of the scrubber system results in increasing depth of anesthesia from hypercapnia-induced hyperventilation.

Clinical manifestations. Carbon dioxide produces both acute and subacute poisoning syndromes. The latter occurs during hypoventilation when a patient fails to eliminate endogenous carbon dioxide, develops hypercapnia, and typically presents with gradual somnolence. This occurrence may be linked to respiratory failure, as in the case of emphysema or opioid poisoning, or it may be iatrogenic, as occurs during permissive hypercapnia.¹³⁸ Alternatively, intense carbon dioxide exposure may produce rapid and lethal poisoning. However, unlike other simple asphyxiants, experimental models of acute carbon dioxide poisoning in which a normal FiO₂ is maintained demonstrate that central nervous and respiratory system manifestations occur within seconds^{89,98} This finding suggests that CO₂ is not solely a simple asphyxiant, but also possesses a potential for systemic effects

Nitrogen (N₂) Gas. Although nitrogen, like carbon dioxide, may produce clinical effects independently of hypoxemia, most poisonings are characterized by the manifestations of simple asphyxiants. Nitrogen gas is used as a carrier gas for chromatography, as a fertilizer, as a cryogenic gas for surgery, and extensively in manufacturing. Poisoning by nitrogen gas is uncommon, but may occur after rapid evaporation of the liquid^{103,104}

Pharmacology and pathophysiology. Nitrogen is a colorless, odorless, and tasteless gas that makes up 78% by volume of air. Under standard conditions, it is an inert diatomic gas that has no direct physiologic toxicity.

Clinical manifestations. Inadvertent connection of air-line respirator hoses to nitrogen and other inert gas sources results in acute asphyxiation, with unconsciousness occurring in approximately 12 seconds^{96,128,188} and death shortly thereafter. More indolent inhalational poisoning by nitrogen is characterized by impairment of intellectual function and judgment, giddiness, and euphoria, which is qualitatively similar to ethanol intoxication¹³¹ More severely poisoned patients may manifest lethargy or coma⁷⁰ Systemic absorption is not rapid, however, and prolonged, high-level exposure is required for poisoning. Nitrogen poisoning, also known as nitrogen narcosis, occurs in underwater divers while they are breathing air that contains 70% nitrogen. It has been called rapture of the deep (l'ivresse des grandes profondeurs) and has led to many deaths in the subaquatic environment. The underlying mechanism of nitrogen narcosis is unknown⁵² but the simple structure and relatively high lipophilicity of nitrogen suggest a mechanism similar to that of the anesthetic gases⁷⁰ To avoid nitrogen narcosis, a less lipid-soluble inert gas such as helium is generally substituted for nitrogen. Substitution with oxygen, although intuitively logical, is inappropriate because of the risk of oxygen toxicity (see Oxygen).

Dermal exposure to liquid nitrogen produces frostbite because of liquid nitrogen's extremely cold temperature.¹⁶⁰ Ingestion of liquid nitrogen similarly produces a freezing injury of the gastrointestinal (GI) tract.^{108,208} Rarely, bubbles introduced through the skin embolize through the vascular system and impair organ blood flow.⁶²

Treatment

Treatment of all individuals poisoned by simple asphyxiants begins with immediate removal of the persons from exposure and provision of ventilatory assistance. Provision of supplemental oxygen is preferable, but room air usually suffices. Hyperbaric oxygen therapy has shown no benefit in the majority of cases. Restoration of oxygenation through spontaneous or mechanical ventilation occurs after only several breaths. Support of vital functions is the mainstay of therapy, but is generally unnecessary after a brief exposure.

PULMONARY IRRITANTS

The irritant gases are a heterogeneous group of chemicals that produce toxic effects via a final common pathway: destruction of the integrity of the mucosal barrier of the respiratory tract (Table 124–2).

TABLE 124–2. Characteristics of Common Respiratory Irritants

<i>Gas</i>	<i>Source or Exposure</i>	<i>Solubility (g%)^a</i>	<i>Detection Threshold (ppm)</i>	<i>Regulatory Standard (ppm)^b</i>	<i>IDLH^c (ppm)</i>	<i>STEL (ppm)</i>
Ammonia	Fertilizer, refrigeration, synthetic fiber synthesis	90	5	50	300	35
Cadmium oxide fumes	Welding	I	Odorless	0.005 mg/m ³	9 mg/m ³ (as Cd)	NA
Carbon dioxide	Exhaust, dry ice sublimation	0.2	Odorless	5000	40,000	30,000
Chloramine	Bleach plus ammonia	M	NA	NR	NR	NR
Chlorine	Water disinfection, pulp, and paper industry	0.7	0.3	0.5	10	1
Copper oxide fumes	Welding	I	NA	0.1 mg/m ³	100 mg/m ³ (as Cu)	NA
Ethylene oxide	Sterilant	M	500	1	800	5
Formaldehyde	Chemical disinfection	M	0.8	0.016	20	2
Hydrogen chloride	Chemical	67	1–5	5	50	5
Hydrogen fluoride	Glass etching, semiconductor industry	M	0.042	3 (as F)	30 (as F)	6
Hydrogen sulfide	Petroleum industry, sewers, manure pits	0.4	0.025		100	50
Mercury vapor	Electrical equipment, thermometers, catalyst, dental fillings, metal extraction, heating or vacuuming elemental mercury	I	Odorless	0.1 mg/m ³	10 mg/m ³	0.05

Methane	Natural heating gas, swamp gas	3.3	Odorless	NR	NR	NR
Methyl bromide	Fumigant	2	20	20	250	NA
Nickel carbonyl	Nickel purification, nickel coating, catalyst	0.05	1–3	0.001	2 (as Ni)	0.1
Nitrogen		0.017	Odorless	NR	NR	NR
Nitrogen dioxide	Chemical synthesis, combustion emission	P	0.12	3	20	5
Nitrous oxide	Anesthetic gas, whipping cream dispensers (abuse), racing fuel additive	0.07	2	25	100	NA
Ozone	Disinfectant, produced by high-voltage electrical equipment	0.001	0.05	0.1	5	0.1
Phosgene	Chemical synthesis, combustion of chlorinated compounds	P	0.5	0.1	2	0.1
Phosphine	Fumigant, semiconductor industry	P	2	0.3	50	1
Propane	Liquefied propane gas	0.007	Odorless	1000	2100	NR
Sulfur dioxide	Environmental exhaust	23	1	2	100	5
Zinc chloride fumes	Artificial smoke (no longer in use)	432	NA	1 mg/m ³	50 mg/m ³	2 mg/m ³
Zinc oxide	Welding	0.16	Odorless	5 mg/m ³	500 mg/m ³	10 mg/m ³

1g/L = grams of gas per 100 mL water, if applicable. * Standards are either Threshold Limit Value–Time Weighted Average (TLV–TWA) set by the American Conference of Governmental Industrial Hygienists (ACGIH) or permissible exposure limits (PELs) set by the Occupational Safety and Health Administration (OSHA). † Immediately dangerous to life and health (IDLH; National Institute for Occupational Safety and Health (NIOSH), revised 1995. (Documentation for each IDLH is available at <http://www.cdc.gov/niosh/idlh/idlhintr.html>.)

I = floating; I = insoluble; M = miscible; NA = not available; NR = no regulatory standard; P = poor; STEL = short-term exposure limit, 15 minute average not to be exceeded.

Pathophysiology

In the lung, irritant chemicals damage both the more prevalent type I pneumocytes and the surfactant-producing type II pneumocytes.¹¹¹ Neutrophil influx, recruited in response to macrophage-derived inflammatory cytokines such as tumor necrosis factor (TNF)- α , releases toxic mediators that disrupt the integrity of the capillary endothelial cells.^{121,158} This host defense response results in accumulation of cellular debris and plasma exudate in the alveolar sacs, producing the characteristic clinical findings of the acute respiratory distress syndrome (ARDS). The specific mechanisms by which the irritant gases damage the pulmonary endothelial and epithelial cells vary. Many irritant gases require dissolution in lung water to liberate their ultimate toxicant, which often is an acid, as occurs when hydrogen chloride gas produces hydrochloric acid. The exact mechanism by which acids damage cells and induce an inflammatory response remains uncertain. Oxidation of intracellular proteins may result in rapid cytoskeletal shortening, creating spaces between endothelial cells and allowing fluid movement into the alveolar spaces.¹⁹⁴ Other gases, such as oxygen and ozone, induce pulmonary damage solely through free radical-mediated oxidative stress on the cellular membranes. Nitrogen dioxide (NO₂) and chlorine are characteristic of a group of gases that produce both acid and free radical oxidants. Furthermore, other respirable xenobiotics, such as metals, injure the respiratory tract through oxidant stress and other mechanisms. Because the precise toxicologic and pathophysiologic effects vary widely depending on the physicochemical properties of the xenobiotic, these mechanisms are covered more completely in the following specific discussions.

By virtue of its use as a war agent, phosgene has received more investigation than the other irritant gases. Although the specific mechanisms of toxicity of the other irritants remain poorly defined, they likely cause injury through a similar process. The acids liberated upon dissolution in the mucosal water react with functional groups on epithelial and endothelial cell membranes and, via cellular messengers, result in a complex inflammatory response.^{170,145} Phosgene stimulates the synthesis of lipoxygenase-derived leukotrienes and other cytokines such as TNF- α .¹⁷⁰ Leukotrienes are important chemotactic factors for neutrophils, which accumulate, liberate oxidants, and produce ARDS.⁹⁷ ARDS can be prevented in rabbits by tomelukast, a leukotriene receptor antagonist,⁸⁵ and by methylprednisolone, which blocks leukotriene synthesis; both of which are beneficial postexposure.⁸⁵ Ibuprofen, an inhibitor of the arachidonic acid cascade, and xenobiotics capable of reducing neutrophil influx, such as colchicine and cyclophosphamide, reduce lung injury and

mortality in mice when they are administered shortly after phosgene exposure.^{77,172} Intratracheal dibutyryl cyclic adenosine monophosphate (DBcAMP), a cAMP analog, and other cAMP amplifiers, such as terbutaline or aminophylline, inhibit the release of leukotrienes and reduce toxicity.^{102,173} When administered 45 minutes after exposure to phosgene-poisoned rabbits, intratracheal N-acetylcysteine (NAC) decreases the formation of leukotrienes by an undefined means and limits the development of ARDS.¹⁷⁴ Presumably, administration via nebulization would prove similarly effective. Intravenous administration of NAC to patients with mild to moderate ARDS, none of whom had phosgene-induced pulmonary damage, improved systemic oxygenation and reduced their need for ventilatory support.¹⁹⁰ However, progression to respiratory failure was not altered.

Free radicals are highly reactive molecular derivatives, typically from oxygen or nitrogen which bind to and destroy tissue near their site of generation. Through initiation of a lipid peroxidative cascade, free radicals destroy lipid membranes and inhibit energy production through the electron transport chain (Chap. 12). Products of lipid peroxidation and cellular damage initiate neutrophilic influx, presumably in an immunologic attempt to combat a pathogen. Ironically, free radicals generated by the invading inflammatory cells contribute to pulmonary damage. Fortunately, the lung has both enzymatic (eg, superoxide dismutase, glutathione peroxidase, catalase) and nonenzymatic (eg, glutathione, ascorbate) antioxidant systems, which detoxify virtually all free radicals present in the lung.¹⁵⁴ However, the oxidant burden imposed by oxidant gases can preempt these detoxifying systems and produce cellular damage. For example, nebulization of manganese superoxide dismutase into the airway one hour after smoke inhalation, a form of oxidant lung injury, did not improve lung edema or pulmonary gas exchange.¹¹⁹ However, the observed benefit of NAC may also be related to improved hemodynamic function (Antidotes in Depth: A3).⁹¹

Clinical Manifestations

Regardless of the mechanism by which the mucosa is damaged, the clinical presentations of patients exposed to irritant gases are similar. Those exposed to gases that result in irritation within seconds generally develop mucosal injury limited to the upper respiratory tract. The rapid onset of symptoms is usually a sufficient signal to the patient to escape the exposure. Patients may present with nasal or oropharyngeal pain in addition to drooling, mucosal edema, cough, or stridor.¹⁹³ Conjunctival irritation or chemosis, as well as skin irritation, is often noted because concomitant ocular and cutaneous exposure to the gases usually is unavoidable. Gases that are less rapidly irritating may not provide an adequate signal of their presence and may not prompt expeditious escape by the exposed individual. In this case, prolonged breathing allows entry of the toxic gas farther into the bronchopulmonary system, where delayed toxic effects may subsequently be noted. Tracheobronchitis, bronchiolitis, bronchospasm, and ARDS are typical inflammatory responses of the airway and represent the spectrum of acute lower respiratory tract injury.

Experimental models assessing the water solubility of a gas to predict the location of its associated lesions have largely agreed with the clinical data.¹⁰⁵ However, exceptions to this relationship of a gas and its expected toxicity are common. For example, in situations in which escape from ongoing exposure is prevented, patients may develop lower respiratory tract injury after prolonged exposure to acutely irritating gases. Alternatively, rapid onset of upper respiratory irritation may be noted in patients after exposure to concentrated gases that are generally associated with delayed symptomatology. Exposure to exceedingly high concentrations of any irritant gas may produce hypoxemia analogous to that resulting from exposure to a simple asphyxiant gas.

The most characteristic and serious clinical manifestation of irritant gas exposure is ARDS.^{13,20,162,163} ARDS consists of the clinical, radiographic, and physiologic abnormalities caused by pulmonary inflammation and alveolar filling that must be both acute in onset and not attributable solely to pulmonary capillary hypertension as occurs in patients with congestive heart failure.^{13,20,162,163} ARDS is a nonspecific syndrome resulting from diverse physiologic insults such as sepsis or trauma. Patients with ARDS may present with dyspnea, chest tightness, chest pain, cough, frothy sputum, wheezing or crackles, and arterial hypoxemia. Typical radiographic abnormalities include bilateral pulmonary infiltrates with an alveolar filling pattern and a normal cardiac silhouette that differentiate this syndrome from congestive heart failure.

In 2012, the diagnostic criteria for ARDS was updated as a consensus guideline known as the Berlin Definition.^{9,10} The draft definition proposed three mutually exclusive strata of ARDS based on the degree of hypoxemia (Table 124–3). Some essential changes of the new definition include: acute was defined as one week or less; the term acute lung injury (ALI) was discontinued; measuring the PaO₂/FiO₂ ratio now requires a specific amount of positive end-expiratory pressure (PEEP); chest radiograph criteria have been clarified to improve interrater reliability; the pulmonary capillary wedge pressure (PCWP) criterion was removed; and additional clarity was added to improve the ability to exclude cardiac causes of bilateral infiltrates.

TABLE 124–3. The Berlin Definition of Acute Respiratory Distress Syndrome^{9,10}

Characteristic	Definition
Timing	Within one week of a known clinical insult, or new or worsening respiratory symptoms
Chest imaging	Bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload Need objective assessment (eg, echocardiography) to exclude hydrostatic edema if no risk factor present
Oxygenation/hypoxemia	
Mild	$200 < \text{PaO}_2/\text{FiO}_2 \leq 300$ with PEEP or CPAP ≥ 5 cm H ₂ O
Moderate	$100 < \text{PaO}_2/\text{FiO}_2 \leq 200$ with PEEP ≥ 5 cm H ₂ O
Severe	$\text{PaO}_2/\text{FiO}_2 \leq 100$ with PEEP ≥ 5 cm H ₂ O

Specific Xenobiotics

Acid-or Base-Forming Gases Highly Water-Soluble Xenobiotics

Ammonia (NH₃). Ammonia is a common industrial and household chemical used in the synthesis of plastics and explosives, and as a fertilizer, a refrigerant, and a cleaner. The odor is characteristic and may be an effective warning signal of exposure and stimulus to avoid further exposure. Dissolution of NH₃ in water to form the base ammonium hydroxide (NH₄OH) rapidly produces severe upper airway irritation. Patients with exposures to highly concentrated NH₃ or exposures for prolonged periods may develop tracheobronchial or pulmonary inflammation. Experimental inhalation of nebulized high-dose ammonia causes ARDS within 2 minutes of exposure¹⁷⁹ Ultrastructural study of the lungs from two individuals dying acutely of ammonia inhalation revealed marked swelling and edema of type I pneumocytes consistent with ARDS³⁵ Chronic inhalation of low concentrations of NH₃ or repetitive exposure to high concentrations of ammonia may cause pulmonary fibrosis³¹

Chloramines. This series of chlorinated nitrogenous compounds (Fig. 124–1) includes monochloramine (NH₂Cl), dichloramine (NHCl₂), and trichloramine (NCl₃). The chloramines are most commonly generated by the admixture of ammonia with sodium hypochlorite (NaOCl) bleach, often in an effort to potentiate their individual cleaning powers⁷² Interestingly, the addition of bleach to septic systems may result in liberation of the chloramines after the reaction of bleach with urinary nitrogenous compounds¹²⁹ On dissolution of the chloramines in the epithelial lining fluid, hypochlorous acid (HOCl), ammonia, and oxygen radicals are generated, all of which act as irritants. Although less water soluble than ammonia, the chloramines typically promptly result in symptoms. Because these initial symptoms are often mild, however, they may not prompt immediate escape, resulting in prolonged or recurrent exposure with pulmonary and ocular symptoms predominating⁴¹ Exposure to trichloramine occurs at indoor swimming pools⁴³ and is responsible for inducing permeability changes in the pulmonary epithelium, the consequences of which are not yet understood³⁸

FIGURE 124–1. Chloramine chemistry. (A) Sodium hypochlorite (bleach) plus ammonia form monochloramine and dichloramine. (B) Chloramine dissolves in water to liberate hypochlorous acid; hydrochloric acid; ammonia; and nascent oxygen [O], an oxidant.

Hydrogen chloride (HCl). The largest and most important use of hydrogen chloride gas is in the production of hydrochloric acid. Dissolution of hydrogen chloride gas in lung water after inhalation similarly produces hydrochloric acid^{34,152} Pyrolysis of polyvinyl chloride (PVC), a plastic commonly used in pipe fabrication, generates HCl and is an occupational hazard for firefighters¹⁴¹ By adsorbing to respirable carbonaceous particles generated in the fire, HCl may be deposited in the alveoli and produce pulmonary toxicity.

Hydrogen fluoride (HF). Hydrogen fluoride and its aqueous form, hydrofluoric acid, are used in the gasoline, glassware, building renovation, and semiconductor industries. Hydrogen fluoride gas dissolves in epithelial lining fluid to

form the weak acid hydrofluoric acid. The intact HF molecule is the predominant form in solution, and few free hydronium ions (H_3O^+) are liberated. Low-dose inhalational exposures may result in irritant symptoms^{200,212} and large exposures may cause bronchial and pulmonary parenchymal destruction^{30,200}. Death after inhalation may result from ARDS, but usually is related to systemic fluoride poisoning independent of the route of exposure because of the resultant calcium binding and subsequent hypocalcemia and hyperkalemia^{26,59} (Chap. 107).

Sulfur dioxide and sulfuric acid (SO_2 and H_2SO_4). Sulfur dioxide has multiple industrial applications and is a byproduct found in the smelting and oil refinery industries. It may also be generated by the inadvertent mixing of chemicals, such as an acid with sodium bisulfite (NaHSO_3). Sulfur dioxide is highly water soluble and has a characteristic pungent odor that provides warning of its presence at concentrations well below those that are irritating. In the presence of catalytic metals (Fe, Mn), environmental sulfur dioxide is readily converted to sulfurous acid (H_2SO_3) within water droplets. Sulfurous acid is a major environmental concern and the cause of “acid rain.” Exposure to atmospheric sulfur dioxide results in a roughly dose-related bronchospasm, which is most pronounced and difficult to treat in patients with asthma. Inhalation of sulfurous acid or dissolution of sulfur dioxide in epithelial lining fluid produces typical pathologic and clinical findings associated with ARDS¹⁵⁹. In addition to the effect of acid generation upon dissolution, sulfur dioxide may cause oxidative damage to the lungs¹²⁷. Large acute exposure to either xenobiotic produces the expected acute irritant response of both the upper and lower respiratory tracts⁴⁴ and pulmonary dysfunction (see Asthma and Reactive Airways Dysfunction Syndrome) may persist for several years¹⁴⁹.

Intermediate Water-Soluble Xenobiotics

Chlorine (Cl_2). Chlorine gas is a valuable oxidizing agent with various industrial uses, and occupational exposure is common. Chlorine gas was used as a chemical warfare agent by both the French and the Germans in World War I (Chap. 132). Although chlorine gas is not generally available for use in the home, domestic exposure to chlorine gas is common. The admixture of an acid to bleach liberates chlorine gas (Fig. 124–2)^{80,135}. Because the anionic component of the acid is not involved in the reaction, combining hypochlorite with virtually any acid, such as phosphoric, hydrochloric, or sulfuric acid, may result in the release of chlorine gas. As such, inappropriate mixing of cleaning products is the cause of most nonoccupational exposures¹³⁵. Rarely, patients have intentionally generated chlorine gas in this manner for purportedly “pleasurable” purposes¹⁵⁵. Concentrated chlorine gas may be generated when aging swimming pool chlorination tablets, such as calcium hypochlorite [$\text{Ca}(\text{OCl}_2)$] or trichloro-s-triazinetriene (TST), decompose^{118,213} or are inadvertently introduced to a swimming pool while swimmers are present^{15,205}. Inadvertent mixture of $\text{Ca}(\text{OCl}_2)$ and TST results in excessive chlorine gas generation and may also be explosive¹¹⁸. Acute chlorine toxicity may occur when there is a failure of the system when compressed chlorine gas is used for direct chlorination of public swimming pools^{15,204} or for drinking water systems. Occasional mass poisoning may occur during scientific, industrial, or transportation incidents^{42,198}.

FIGURE 124–2. Chlorine chemistry. (A) Formation of chlorine gas from the acidification of hypochlorous acid. (B) Dissolution of chlorine in mucosal water to generate both hydrochloric and hypochlorous acids (HCl and HOCl) and oxidants [O].

Mass exposure has also been reported when a chlorine storage tank was being recycled, and it ruptured.⁴⁰ The odor threshold for chlorine is low, but distinguishing toxic from permissible air concentrations may be difficult until toxicity is manifest. The intermediate solubility characteristics of chlorine result in only mild initial symptoms after moderate exposure and permit a substantial time delay, typically several hours, before clinical symptoms develop. Chlorine dissolution in lung water generates HCl and hypochlorous (HOCl) acids. Hypochlorous acid rapidly decomposes into HCl and nascent oxygen (O). The unpaired nascent oxygen atom produces additional pulmonary damage by initiating a free radical oxidative cascade. Although the majority of life-threatening chlorine poisonings occur after acute, large exposures, patients with chronic, low-concentration exposure or recurrent, moderate concentration poisonings may manifest increased bronchial responsiveness.^{5,69,76}

Hydrogen sulfide (H_2S). Hydrogen sulfide exposures occur most frequently in the waste management, petroleum, and natural gas industries⁹² although poisoning occurs in asphalt, synthetic rubber, and nylon industry workers as well. It is also rarely seen in hospital workers using acid cleaners to unclog drains clogged with plaster of Paris sludge¹⁴⁸. Hydrogen sulfide is present in natural sources such as volcanic emission, in caves, and in sulfur springs. It is a decay product of organic material found in sewers or manure pits. Hydrogen sulfide, hydrogen fluoride, and phosphine are differentiated

from the other irritant gases by their ability to produce significant systemic toxicity. Hydrogen sulfide inhibits mitochondrial respiration in a fashion similar to that of cyanide (Chap. 126^{64,157}

H₂S has the distinctive odor of “rotten eggs,” which, although helpful in diagnosis, is not specific. Despite a sensitive odor threshold of several parts per billion,¹⁵⁷ rapid olfactory fatigue ensues, providing a misperception that the exposure and its attendant risk have diminished. At low and moderate concentrations (≤ 500 ppm), upper respiratory tract mucosal irritation occurs and is the principal toxicity.¹⁹² The rapidity of death in patients exposed to high H₂S concentrations makes it likely that either simple asphyxiation or cytochrome oxidase inhibition is causal in most cases.

Phosgene (carbonyl chloride {COCl₂}). During World War I, phosgene was an important weapon of mass destruction that produced countless deaths (Chap. 132). Currently, phosgene is used in the synthesis of various organic compounds, such as isocyanates, and it occasionally produces poisoning. It is a byproduct of heating or combustion of various chlorinated organic compounds¹⁸¹

Exposure to phosgene initially may produce limited manifestations, but may result in acute mucosal irritation after intense exposure. In fact, the pleasant odor of fresh hay, rather than prompting escape, ironically may promote deep and prolonged breathing of the toxic gas. The most consequential clinical effect related to phosgene exposure is delayed ARDS.^{27,169} Because of the accumulation of a significant alveolar burden of phosgene, symptoms generally are severe after they occur. The delay in onset may take up to 24 hours, so prolonged observation of patients thought to be phosgene-poisoned is warranted. The mechanism of phosgene toxicity is dependent on the dissolution of the gas into the fluid of the epithelial lining with resultant liberation of hydrochloric acid and reactive oxygen species (ROS).¹⁶⁹

Oxidant Gases. Rather than acidic or alkaline metabolites, free radicals mediate the pulmonary toxicity of certain irritant gases. Many of the chemicals discussed participate in both acid–base and oxidant types of injury. However, the clinical distinction between acid-or alkali-forming agents and oxidant gases is difficult but ultimately may prove therapeutically relevant.

Oxygen (O₂). Oxygen toxicity is uncommon in the workplace but, ironically, is common in hospitalized patients. Although O₂ may produce CNS and retinal toxicity, pulmonary damage is more common.¹⁸⁰ Several clinical studies indicate that humans can tolerate 100% O₂ at sea level for up to 48 hours without significant acute pulmonary damage.^{37,56} Under hyperbaric conditions (2.0 atmospheres absolute), such as during compressed-air diving or while inside a pressurized hyperbaric chamber, oxygen toxicity may develop within 3 to 6 hours.⁴⁷ ARDS occurs in approximately 5% of patients administered hyperbaric oxygen for therapeutic purposes.¹⁸⁰ Delayed pulmonary fibrosis, presumably from healing of subclinical injury, may develop in patients breathing lower concentrations of O₂ at sea level for shorter periods.

Although it appears paradoxical that O₂, an essential molecule, may be deleterious at elevated concentrations, it is not. In mitochondria, O₂ plays a critical role as the ultimate acceptor for electrons completing the electron transport chain. It is this same potent oxidizing activity that allows O₂ to remove electrons from other compounds generating the reactive oxygen intermediates.¹⁶⁴

Generation of ROS, including superoxide (O₂^{•−}), hydroxyl radical (OH[•]), hydrogen peroxide (HOOH), singlet oxygen (O[•]), and nitric oxide (NO), produces cellular necrosis, increases pulmonary capillary permeability, and induces apoptosis.^{142,164} NO, produced by inducible NO synthase (iNOS) in the setting of oxidative stress, is directly cytotoxic or may combine with superoxide anions to form the more reactive oxidant peroxynitrite (ONOO[−]).⁹³ Experimental prevention of these effects by administration of either parenteral NAC,^{165,207} a chemical antioxidant, or superoxide dismutase, an enzymatic antioxidant,^{37,199} suggests that the mechanism of toxicity relates to the oxidant, or electrophilic, effects of these ROS (Chap. 12). Although several other therapies have shown promise in preventing oxygen-mediated toxicity, none has yet proven to be valuable for patients who already manifest pulmonary toxicity. Current techniques for preventing pulmonary oxygen toxicity emphasize reduction of the inspired oxygen concentration by use of PEEP ventilation, although this approach failed to prove beneficial in at least one clinical trial.¹⁴ The potential role of liquid ventilation of the lung with perfluorocarbons to prevent or treat pulmonary oxygen toxicity remains under investigation.¹⁴

Oxides of nitrogen (NO_x). Oxides of nitrogen are a series of variably oxidized nitrogenous compounds.⁷³ The most important substances included in this series are the stable free radicals nitrogen dioxide (NO₂) and nitric oxide (NO), as well as nitrogen tetroxide (dinitrogen tetroxide [N₂O₄]), nitrogen trioxide (N₂O₃), and nitrous oxide (N₂O). The oxides of nitrogen are of limited value in industrial operations, although they may be generated during welding and brazing. NO₂, in addition to hydrogen cyanide, is produced in the pyrolysis of nitrocellulose, which is a substantial component of radiographic film. For example, a fire in the radiology department of the Cleveland Clinic in 1929 resulted in 125 casualties, with virtually all deaths resulting from cyanide or NO₂ gas poisoning.⁸² NO₂ toxicity may occur when propane-driven ice-cleaning machines are used in indoor ice skating rinks with poor ventilation, thereby allowing accumulation of the generated NO₂.¹¹⁴ Military exposure to high NO₂ concentrations may occur during closed-space fires, such as in

submarines¹²⁰ NO₂ also causes silo filler's disease, in which the toxic gas generated during decomposition of silage accumulates within the silo shortly after grain storage, eliminating rodents that feast on the grains^{60,215} In the absence of ventilation, high concentrations of NO₂ may accumulate in the silo such that an individual entering the silo is rapidly asphyxiated from the depletion of oxygen⁸³ Additionally, substantial quantities of NO₂ remaining after incomplete ventilation may produce the delayed-onset pulmonary toxicity characteristic of silo filler's disease. Chronic indoor exposure to NO₂, generated during cooking⁹⁹ or outdoor exposure to photochemical smog, of which the oxides of nitrogen are a component, may predispose individuals to the development or exacerbation of chronic lung diseases.

The various oxides of nitrogen may directly oxidize respiratory tract cellular membranes, but more typically generate reactive nitrogen intermediates, or radicals, such as ONOO⁻, which subsequently damage the pulmonary epithelial cells.¹⁴⁶ In addition to generating oxidant cascades, dissolution in respiratory tract water generates nitric acid (HNO₃) and NO, which produce injury consistent with other inhaled acids. In fact, inhalation of HNO₃ produces the same clinical and pathologic syndrome.⁸⁶ Antioxidants afford significant protection to human endothelial cells exposed to NO₂, indicating an important role of free radicals in the toxicology of these xenobiotics.²⁰¹

NO, an endogenous compound important as a neurotransmitter and vasorelaxant, is used clinically as exogenous inhalational therapy for pulmonary hypertension and ARDS.¹⁹⁵ In patients with ARDS not resulting from sepsis (although not specifically from inhalational injury), low concentrations of inhaled NO (5 ppm) did not improve the clinical outcome.¹⁹⁵ However, one patient with NO₂ pulmonary toxicity improved clinically after NO therapy, so further consideration is warranted.¹¹² Furthermore, its use in premature infants with respiratory distress syndrome is well accepted.¹⁶⁸ NO is less soluble in the fluid lining the epithelial surfaces than are the other oxides of nitrogen and produces irritant effects after large exposures.^{88,211} Its pulmonary oxidative toxicity, the manifestations of which are typical of the oxidant gases, is substantially enhanced by conversion to reactive nitrogen intermediates such as ONOO⁻.¹⁹ This radical selectively interacts with tyrosine to produce nitrotyrosine, which may subsequently serve as a marker for oxidant damage.⁸⁸ NO may be absorbed from the lung and is rapidly bound by hemoglobin to form nitrosylhemoglobin and methemoglobin.

Ozone (O₃). Ozone is abundant in the stratospheric region found between 5 and 31 miles above the planet. Ozone is formed by the action of ultraviolet light on oxygen molecules, thus reducing the amount of solar ultraviolet irradiation reaching earth. The ozone concentration in passenger aircrafts may at times be above regulatory limits¹⁸² although a specific relationship with the development of clinical effects in airline crew members is elusive.¹³⁶ Ozone is another important component of photochemical smog and, as such, contributes to chronic lung disease.^{32,202} It is produced in significant quantities by welding and high-voltage electrical equipment and in more moderate doses by photocopying machines and laser printers. Because of its high electronegativity (only fluorine is higher), ozone is one of the most potent oxidizing agents available. For this reason, it is used as a bleach, particularly as an alternative to chlorine in water purification and sewage treatment.

The pulmonary toxicity associated with ozone primarily results from its high reactivity toward unsaturated fatty acids and amino acids with sulfhydryl functional groups.^{21,101} Ozonation and free radical damage to the lipid component of the membrane initiate an inflammatory cascade, with resultant influx of inflammatory cells.^{22,158} Reactive nitrogen species are also implicated, as NO synthase knockout mice are relatively protected from ozone-induced inflammation and tissue injury.⁶⁷ Increased permeability of the pulmonary epithelium results in alveolar filling from the transudation of proteins and fluids characteristic of ARDS. Antioxidant agents (eg, vitamin E) that react preferentially with free radicals before membrane damage occurs prevent or limit the pulmonary toxicity of ozone.

Miscellaneous Pulmonary Irritants

Methylisocyanate. Methylisocyanate (MIC; Fig. 124–3) is one of a series of compounds sharing a similar isocyanate (N=C=O) moiety. Toluene diisocyanate (TDI) and diphenyl-methane diisocyanate (MDI) are important chemicals in the polymer industry. In those exposed to MIC in Bhopal, ARDS was evident both clinically and radiographically.¹³⁰ MIC is a significantly more potent respiratory irritant than the other regularly used isocyanate derivatives such as TDI.⁶ Cyanide poisoning does not occur, and empiric antidotal therapy is not indicated

FIGURE 124–3. Methylisocyanate.

Riot control agents: capsaicin, chlorobenzylidenemalononitrile, and chloroacetophenone. Historically, riot control

agents (Fig. 132–5), commonly called Mace, consisted primarily of chloroacetophenone (CN) or chlorobenzylidenemalononitrile (CS)²⁴. Both are white solids that are dispersed as aerosols. The dispersion is generally accomplished through mixture with a pyrotechnic agent such as a grenade or with a volatile organic solvent in a personal protection canister. Because the delivery systems of these agents are of limited sophistication and are subject to prevailing environmental conditions, dosing is unpredictable, and unintended self-poisoning is common²⁴. After low-concentration exposure, ocular discomfort and lacrimation alone are expected, accounting for the common appellation tear gas. The effects are transient, and complete recovery within 30 minutes is typical, although long-lasting pulmonary effects may occur (see Asthma and Reactive Airways Dysfunction Syndrome¹⁶¹). Closed-space or close-range exposure, as well as physical exertion during exposure, may produce significant ocular toxicity, dermal burns, laryngospasm, ARDS¹⁹⁶ or death²⁴. Because of their high potential for severe toxicity, CN and CS were replaced for civilian use by oleoresin capsicum (OC), also known as pepper spray or pepper mace. Although capsaicin, its active component, is considerably less toxic, it is occasionally responsible for pneumonitis²³ and death¹⁸⁶.

Capsaicin interacts with the vanilloid receptor-1 (VR1), which was recently renamed the transient receptor potential vanilloid-1 (TRPV1).¹⁹¹ Stimulation of this receptor invokes the release of substance P, a neuropeptide involved with transmission of pain impulses. Substance P also induces neurogenic inflammation, which, in the lung, results in ARDS and bronchoconstriction (see Asthma and Reactive Airways Dysfunction Syndrome).¹⁹¹ The severe pulmonary toxicity of CS and CN likely is related to their ability to alkylate tissues in a manner similar to nitrogen mustard.⁴⁸

Metal pneumonitis. Acute inhalational exposures to certain metal compounds produce clinical effects identical to those of the chemical irritants. For example, zinc chloride (ZnCl₂) fume is used as artificial smoke because of the dense white character of the fume, and an aqueous solution is still used as a soldering flux. Exposure to zinc chloride fumes for just a few minutes is associated with ARDS and death^{66,94,95} (Chap. 103). Cadmium oxide (CdO) is generated during the burning of cadmium metal in an oxygen-containing environment, as occurs during smelting or welding (Chap. 91). The refining of nickel using carbon monoxide (Mond process) produces nickel carbonyl [Ni(CO)₄], a volatile pulmonary oxidant¹⁷⁵ (Chap. 99). Inhalation of volatilized elemental mercury¹³⁴ which occurs during the vacuuming of mercury spills or home extracting of precious metals, may be toxic. Although at sufficient concentrations, many of these metal exposures produce warning symptoms, severe toxicity may occur even in the absence of warning symptoms. The mechanism of toxicity may relate to overwhelming oxidant stress with a pronounced inflammatory response as measured by serum cytokines (eg, TNF-α) concentrations.⁹⁵ Experimental findings suggest a role for inactivation of natural antioxidant systems.²¹⁴ Patients with metal-induced pneumonitis present with chest tightness, cough, fever, and signs consistent with ARDS. Metal pneumonitis is distinguishable from other causes of ARDS only by history or, retrospectively, by elevated serum or urine metal concentrations.⁸ In particular, metal pneumonitis should be differentiated from the more common and substantially less consequential metal fume fever, discussed later in this chapter. In addition to standard supportive measures, patients with acute metal-induced pneumonitis should be hospitalized and receive corticosteroids.⁹⁵ Chelation therapy has no documented benefit for treatment of patients with ARDS, but should be used based on conventional indications.

MANAGEMENT

Standard and Supportive Measures

Management of patients with acute respiratory tract injury begins with meticulous support of airway patency by limiting bronchial and pulmonary secretions and maintaining oxygenation. Although various theoretical and experimental treatment modalities have been proposed, supportive care remains the mainstay of therapy. Supplemental oxygen, bronchodilators, and airway suctioning should be used if clinically indicated. Nitrovasodilators, diuretics, and morphine have little role in the management of patients with ARDS, although low-dose morphine may prove beneficial as an anxiolytic.^{3,150} Corticosteroid therapy, designed to reduce the inflammatory host defense response, frequently improves surrogate markers of pulmonary damage,^{123,124} such as oxygenation status, but generally offers little outcome enhancement in patients with ARDS.^{4,147} Clinical data on the efficacy of corticosteroids used in human beings exposed to pulmonary irritants is limited and inconclusive. There might be some benefit in the first 14 days after an exposure, but methylprednisolone was associated with increased mortality at 60 and 180 days (when steroids were continued after the first 14 days). A recent article reviewed animal studies published from 1966 to January 2010 and did not find a benefit in animal studies, especially after severe exposures.⁵⁴ Importantly, most studies of ARDS involve predominantly septic or traumatized patients, with few patients suffering from inhalational poisoning. Because the inflammatory response initiated by bacterial endotoxin differs from that caused by irritant gases, the applicability of these studies to the treatment of poisoned individuals is limited. There is an interesting report of simultaneous, presumably equivalent chlorine exposure in two sisters, with improved outcome in the sister who received steroid treatment.⁴⁵ Most available research evaluates parenterally administered corticosteroids, although animal models demonstrate a beneficial effect of nebulized beclomethasone^{84,54} and nebulized budesonide^{209,54} after acute chlorine poisoning. Nebulized budesonide compared to

intravenous betamethasone had similar effects.⁵⁴ However, a human pretreatment model of inhaled budesonide fails to document a substantive alteration of the effects of ozone inhalation.¹³⁷ Ketoconazole, an antifungal agent with antiinflammatory effects,¹ and nonsteroidal antiinflammatory agents, such as ibuprofen,¹⁷¹ variably improve experimental lung function or mortality in patients with ARDS of various nontoxicologic etiologies and have little current role in the therapeutic armamentarium. Furthermore, most of the aforementioned studies assess acute outcome and not long-term effects in survivors. Because corticosteroids experimentally reduce the late fibroproliferative phase during lung recovery, they ultimately may prove beneficial. Overall, there is little reason to suspect any specific benefit of corticosteroids and other antiinflammatory drugs in most poisoned patients. However, because most studies demonstrate some benefit and little identifiable risk, corticosteroid use appropriately remains routine and based largely on local practices.

The clinical similarities among patients with irritant gas exposure and other etiologies of ARDS suggest that similar management principles should be applied. Prone positioning during ventilation,^{7,74} PEEP,⁶⁸ and inverse-ratio ventilation are successful in enhancing the oxygenation of patients with ARDS of various causes but are not necessarily successful in improving outcome. Lower tidal volume mechanical ventilation using 6 mL/kg and plateau pressures 30 cm H₂O attenuated the inflammatory response¹⁴³ and resulted in lower mortality and less need for mechanical ventilation than traditional volume ventilation with 12 mL/kg.^{2,132} Although not specifically evaluated in any of these studies, there are sound theoretical reasons to believe that all of these modalities should improve oxygenation in poisoned patients as well. Although it is always important to reduce the inspired concentration of oxygen to below 50% as rapidly as possible, patients poisoned by irritant gases may be even more susceptible to oxygen toxicity as a result of depletion of endogenous antioxidant barriers.¹⁷⁸

Neutralization Therapy

A therapy unique to several of the acid- or base-forming irritant gases is chemical neutralization. Although contraindicated in acid or alkali ingestion, the large surface area of the lung and the relatively small amount of xenobiotic present allow dissipation of the heat and gas generated during neutralization. Case studies suggest that nebulized 2% sodium bicarbonate may be beneficial in patients poisoned by acid-forming irritant gases.²⁰⁴ The vast majority of these cases involve chlorine gas exposure, and most patients received other symptomatic therapies as well.²⁸ Although there appears to be no specific benefit for patients exposed to chloramine, nebulized bicarbonate therapy appears to be safe.¹⁴⁴ A prospective evaluation of patients poisoned with chloramine and chlorine gas did not show any clinically significant difference between the group getting nebulized sodium bicarbonate and the control group, although there was a small but statistical improvement in forced expiratory volume in one second (FEV₁) at 120 and 240 minutes in the group that received nebulized sodium bicarbonate.¹¹ Any sodium bicarbonate solution used should be sufficiently diluted to prevent irritation. Typically, 1 mL of 7.5% or 8.4% sodium bicarbonate solution is added to 3 mL sterile water (resulting in an approximately 2% solution for nebulization).

Whether nebulized sodium bicarbonate therapy alters the natural course of irritant-induced pulmonary damage remains uncertain. The fact that many irritants produce concomitant oxidant injury suggests that it may not. Nebulized 4% sodium bicarbonate administered to chlorine-poisoned sheep improved oxygenation, but failed to decrease mortality rates.⁴⁶ Therefore, patients receiving nebulized bicarbonate therapy require observation beyond the time of symptom resolution. Because administration of neutralizing acids for alkaline irritants, such as ammonia, has not been attempted, their use cannot be recommended at this time (Antidote in Depth: A5).

Antioxidants

Antioxidants include reducing agents such as ascorbic acid, NAC,¹⁰⁶ free radical scavengers such as vitamin E, and enzymes such as superoxide dismutase. Studies in humans have noted both increased¹⁶⁶ and decreased²⁹ endogenous antioxidant concentrations in bronchoalveolar lavage fluid in patients with ARDS. Although the concept of treating pulmonary oxidant stress with antioxidants or free radical scavengers is intriguing, most currently available evidence suggests that these xenobiotics offer negligible benefit.^{133,140} The rapid onset of the self-perpetuating destructive effects initiated by redox reactions may hinder any postexposure therapy. This interpretation is supported by pretreatment models in which antioxidants are effective at preventing or at least limiting the pathologic effects. Use of these and other newer therapies targeted against inflammatory mediators or the oxidative cascade are in the earliest investigative stages.

Xenobiotic-Directed Therapy

Patients with inhalational exposure to hydrogen fluoride should undergo frequent electrocardiographic evaluations and correction of serum electrolytes. Administration of nebulized 2.5% calcium gluconate, prepared as 1.5 mL 10% calcium gluconate plus 4.5 mL 0.9% sodium chloride solution or sterile water, should be considered to limit systemic fluoride absorption.^{107,113,200} By binding fluoride ion locally, nebulized calcium may prevent fluoride-induced cellular and systemic

toxicity. Systemic calcium salts should be administered as needed to correct hypocalcemia ([Chap. 107](#) and Antidotes in Depth: A29).

Current therapy for inhalation of capsaicin, or of any tear gas, is primarily supportive. Extracorporeal membrane oxygenation has been used in children to maintain oxygenation in the presence of severe pulmonary toxicity resulting from capsaicin exposure.²³ Although no antidotes currently are available, the newly developing insight into the receptor mechanism of capsaicin suggests that a receptor active agent may hold future promise.

Advanced Pharmacologic Therapy

Perfluorocarbon Partial Liquid Ventilation. Partial liquid ventilation involves the intrapulmonary administration of perfluorocarbons, which are inert liquids with low surface tension and excellent oxygen-carrying capacity. Studies in patients with nonchemically induced ARDS suggest that exfoliated tissue, and presumably persistent xenobiotic, may be effectively lavaged from the bronchopulmonary tree with this method.⁵¹ Perfluorocarbons improve oxygenation and may have an antiinflammatory effect, as demonstrated by reduced oxidant lung injury after liquid ventilation in animals.⁵⁰ Although it may prove to be a highly useful therapy in the future, the limited availability, high cost, and lack of demonstrated efficacy of this therapy make it suitable only for academic and research settings.⁵¹

Exogenous Surfactant

Several other developments may prove useful in the general management of patients with ARDS. Surfactant replacement therapy initially received attention as a treatment for patients with ARDS because of its beneficial effects in infant respiratory distress syndrome. Although several experimental and clinical studies suggested the safety and efficacy of surfactant therapy in patients with ARDS, large randomized, controlled clinical trials fail to show a benefit on survival.¹⁸⁴ Patients who received surfactant had a greater improvement in gas exchange during the 24-hour treatment period than patients who received standard therapy alone, suggesting the potential benefit of a longer treatment course.¹⁸⁴ But because most studies involved patients with sepsis-related ARDS, the inability to show a beneficial effect may not adequately reflect the potential of surfactant in irritant gas-induced ARDS.¹⁵¹ Many oxidant gases inactivate endogenous surfactant, although the specific effects on exogenous surfactant are not well understood.¹⁵¹

Nebulized Epinephrine. There are early studies being performed in animal models to evaluate the efficacy of nebulized epinephrine to attenuate the acute injury to lung tissue caused by smoke inhalation. A study in sheep suggests that nebulized epinephrine (4 mg) attenuates pulmonary dysfunction and decreases pulmonary hyperemia without systemic effects like hyperglycemia and elevated plasma catecholamines.¹¹⁰

OTHER INHALED PULMONARY XENOBIOTICS

A particulate, or dust, is a solid dispersed in a gas. Dust is a substantial source of occupational particulate exposure and is an important cause of acute pulmonary toxic syndromes. A respirable particulate must have an appropriately small size (generally <10 microns) and aerodynamic properties to enter the terminal respiratory tree. Nonrespirable particulates, also called nuisance dusts, are trapped by the upper airways and are not generally thought to cause pulmonary damage. In distinction from the irritant gases, there is no unifying toxic mechanism among the respirable particulates. Many of the particulate diseases, such as asbestos exposure and its sequelae, are chronic in nature; only the acute or subacute syndromes are discussed here.

Inorganic Dust Exposure

Silicosis is a range of pulmonary diseases associated with inhalation of crystalline silica (SiO_2), or quartz. It typically occurs in workers involved in occupations in which rock or granite is pulverized, including mining, quarry work, and sandblasting. Although typically a chronic disease, intense subacute exposure may produce acute silicosis in a few weeks and death within 2 years. The mechanism of toxicity probably relates to the relentless inflammatory response generated by the pulmonary macrophages.¹³⁹ These cells engulf the indigestible particles and are destroyed, releasing their lytic enzymes and oxidative products locally within the pulmonary parenchyma. Patients present with dyspnea, cor pulmonale, restrictive lung findings, and classic radiographic findings. Treatment is limited and includes steroids and supportive care.

Silica combined with other minerals is referred to as silicates, the most important of which include asbestos and talc. Talc, or magnesium silicate [$(\text{Mg}_3\text{Si}_4)\text{O}_{10}(\text{OH})_2$], is widely used in industry, but its use in the home has been curtailed over the past two decades because of cases of severe pulmonary injury.¹¹⁷ Much of the toxicity of talc is related to free silica or asbestos contamination. Improvement after acute massive exposure may be accompanied by progressive pulmonary fibrosis.

Organic Dusts

Inhalation of dusts from cotton or similar natural fibers, usually during the refinement of cotton fibers (byssinosis), produces chest tightness, dyspnea, and fever that typically begin within 3 to 4 hours of exposure. Similar reactions may occur after inhalation of hay, silage, grain, hemp, or compost dust. Symptoms often resolve during the workweek but return after a weekend hiatus. Byssinosis is probably caused by an endotoxin present on the cotton and is not immunologic in nature.²¹⁰ “Grain fever” is caused by a respirable compound associated with grain dust, as occurs during harvesting, milling, and transporting.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is the final common pathway for many different organic dust exposures.¹⁸⁷ The name attached to the individual syndrome typically identifies the associated occupation or substrate. For example, bagassosis is the term associated with sugar cane (bagasse), and farmer’s lung is the term associated with moldy hay, although both conditions are caused by thermophilic *Actinomyces* spp. When associated with puffball mushroom spores (*Lycoperdon* spp), the syndrome is called lycoperdonosis ([Chap. 120](#)); when caused by bird droppings, it is called bird fancier’s lung. The implicated allergen is capable of depositing in the pulmonary parenchyma and eliciting a cell-mediated (type IV) immunologic response. Clinical findings include fever, chills, and dyspnea beginning 4 to 8 hours after exposure. The chest radiograph usually is normal, but may reveal diffuse or discrete infiltrates. Progressive disease is associated with a honeycombing pattern on the radiograph and a restrictive lung disease pattern on formal pulmonary function testing. Treatment includes corticosteroids and avoidance of the antigen.

Metal Fume Fever and Polymer Fume Fever

Metal fume fever is a recurrent influenzalike syndrome that develops several hours after exposure to metal oxide fumes generated during welding, galvanizing, or smelting. Although most symptoms of metal fume fever are similar to those expected with irritant gas exposures (dyspnea, cough, chest pain), the presence of fever, typically 100.4°F to 102.2°F (38°C–39°C), distinguishes the syndromes.²⁵ In addition, patients may experience headache, metallic taste, myalgias, and chills. Direct pulmonary toxicity probably does not occur, and patients with metal fume fever generally have normal chest radiographs. Interestingly, acute tolerance develops, so repeat daily exposures produce progressively milder symptoms. However, the tolerance disappears rapidly, and after a short work hiatus such as a weekend, the original intensity resumes, thus accounting for the designation “Monday morning fever.” Many metal oxides are capable of eliciting this syndrome, but it is noted most frequently in patients who have welded galvanized steel, which contains zinc. Metal fume fever also occurs commonly after the high-temperature welding of copper-containing compounds, thus accounting for the historical appellation “brass foundry workers’ ague.” There is a strong association between welding-related metal fume fever and welding-related respiratory symptoms suggestive of occupational asthma.⁶⁵ Serum and urine metal concentrations typically are not elevated after the acute event, although they may be chronically elevated from daily occupational exposure. The etiology of metal fume fever is debated, but the syndrome has features suggestive of both an immunologic and a toxic etiology.²⁵ Antigen release with immunologic response appears to be responsible for the induction of symptoms. On subsequent exposure, proinflammatory cytokines, such as TNF- α , and various interleukins can be detected in bronchoalveolar lavage fluid.¹⁰⁹ However, because symptoms may occur with the first exposure to fumes, a direct toxic effect on the respiratory mucosa presumably exists.¹²² Exposure to certain metal fumes, such as cadmium oxide or other zinc compounds, may produce direct toxic effects on the pulmonary parenchyma.¹²²

The management of patients with metal fume fever is supportive and includes analgesics and antipyretics. There is no specific antidote, and chelation therapy should not be instituted unless otherwise indicated; patients with ARDS probably have metal toxicity (eg, cadmium pneumonitis). The natural course of metal fume fever involves spontaneous resolution within 48 hours. Persistent symptoms are rare and should prompt investigation for metal toxicity.

A remarkably similar syndrome occurs subsequent to inhaling pyrolysis products of fluorinated polymers (eg, Teflon), which is aptly termed polymer fume fever.¹⁷⁷ Patients develop self-limited viral illness-type symptoms several hours after exposure to the fumes. As with metal fumes, very large exposures to polymer fumes may result in direct pulmonary toxicity. Supportive care is the therapy of choice.

Asthma and Reactive Airways Dysfunction Syndrome

Asthma, or reversible airways disease, is a clinical syndrome that includes intermittent episodes of dyspnea, cough, chest pain or tightness, wheezes on auscultation, and measurable variations in expiratory airflow. Episodes typically are triggered by a xenobiotic or physical stimulus and resolve over several hours with appropriate therapy. The underlying process is immunologic in most cases, with allergen-triggered release of inflammatory mediators causing bronchiolar smooth muscle contraction and subsequent inflammation. Because asthma affects 5% to 10% of the world’s population and the triggers often are nonspecific, it is not surprising that work-aggravated asthma is extremely common. The patients are

previously sensitized, and the initial irritant exposure causes bronchospasm or similar symptoms. Thus, work-aggravated asthma is discovered early in the worker's employment, and a more appropriate workplace or occupation can be pursued.

Occupational asthma, or asthma occasioned by a workplace exposure to a sensitizing xenobiotic, accounts for perhaps 10% to 17% of all newly diagnosed asthma in adults.^{115,197} Casual exposure to one of the 250 or more known sensitizers (Table 124-4) is usually associated with a latency period of weeks or months of exposure before symptom onset. After symptoms begin, however, they recur consistently after reexposure to the inciting trigger agent. Occupational asthma with latency may be IgE dependent, in which case it is identical to allergic asthma, or is IgE independent.²⁰³ The IgE-dependent form is most commonly associated with high-molecular-weight compounds (>5000 Da) or with certain haptenic low-molecular-weight agents (eg, acetic anhydride). The low-molecular-weight agents (eg, nickel, isocyanates) more typically cause IgE-independent disease, which manifests as the delayed reaction pattern of cell-mediated, or type IV, hypersensitivity. Because contact with a trigger may be difficult to avoid in either case, reassignment or an outright occupational change may be required. Treatment for exacerbations is comparable to standard asthma therapy and includes bronchodilators and corticosteroids.

TABLE 124-4. Common Xenobiotic Sensitizers Producing Occupational Asthma

<i>Molecular Weight</i>	<i>Example</i>	<i>Primary Risk Occupations</i>
High		
Proteins	Crab shell protein	Seafood processors
Low		
Acrylate	—	Adhesives, plastics
Glutaraldehyde	—	Health care workers
Isocyanates	Toluene diisocyanate	Polyurethane foam, automobile painters
Metals	Nickel sulfate	Nickel platers
Trimellitic anhydride	—	Chemical workers
Wood dust	Western red cedar (<i>Thuja plicata</i>)	Foresters, carpenters

Acute exposure to irritant gas may result in the development of a persistent asthmalike syndrome also termed reactive airways dysfunction syndrome (RADS), irritant-induced asthma, or occupational asthma without latency. Virtually every irritative xenobiotic is reported to cause this syndrome, and those not yet described probably are simply unrecognized. Although asthma typically is associated with massive inhalational exposure, as occurred after the World Trade Center collapse,¹⁶ occasional patients are susceptible to low-level exposure.³³ RADS is often compared to occupational asthma because both disorders are chemically induced and most frequently occur after chemical exposure in the workplace.⁴⁹ However, in comparison with those who develop occupational asthma, patients who develop RADS have a lower incidence of atopy and are exposed to agents not typically considered to be immunologically sensitizing.³³ In addition, the airflow improvement with β_2 -adrenergic agonist therapy is significantly better in patients with occupational asthma.⁷⁵ Bronchial biopsy performed in patients with RADS generally reveals a chronic inflammatory response.⁷⁵ RADS may have a neurogenic etiology,¹²⁵ as opposed to an immunologic origin as in patients with occupational asthma, which may differentiate these clinically similar diseases on a mechanistic basis. Neurogenic inflammation results from increased vascular permeability, presumably secondary to release of substance P from unmyelinated sensory neurons (C fibers).⁵⁸ Neurogenic inflammation is inhibited by substance P depletors, such as capsaicin, and enhanced by substances that inhibit neutral endopeptidase, the enzyme responsible for degradation of substance P.¹²⁶ The role of corticosteroids is undefined, but animal models suggest an antiinflammatory benefit, and they are widely used.⁵⁵ Recovery may take months, with the delay related to either ongoing low-level exposures to endopeptidase inhibitors or persistent irritation of impaired tissue by environmental irritants such as pollution.

SUMMARY

- Although the spectrum of xenobiotics capable of causing pulmonary toxicity is large, the pathologic changes are rather limited.
- Gases that have little or no irritant potential or systemic toxicity cause simple asphyxiation, in which the ambient atmosphere has a diminished oxygen concentration.

- Parenchymal irritation occurs after exposure to acid forming or free radical generating gases and may progress to severe toxicity manifesting as ARDS.
- RADS is described in patients after exposure to virtually all of the irritant gases.
- Treatment of all such exposures centers on symptomatic and supportive care.

125 CARBON MONOXIDE

Christian Tomaszewski

Carbon Monoxide (CO)	
MW	= 28.01 Da
Gas density	= 0.968 (air = 1.0)
Blood carboxyhemoglobin level	
Nonsmokers	= 1%–2%
Smokers	= 5%–10%
Action level	> 10%
TLV–TWA	= 50 ppm

HISTORY AND EPIDEMIOLOGY

Carbon monoxide (CO) is formed during the incomplete combustion of virtually any carbon-containing compound. Because it is an odorless, colorless, and tasteless gas, it is remarkably difficult to detect in the environment even when present at high ambient concentrations and is a leading cause of poisoning morbidity and mortality in the United States. Based on US national death certificate data, there were 439 annual deaths from unintentional non-fire exposure to CO from 1999 to 2004.^{25,123} The groups with the highest risk were male gender and elderly age, possibly because of occupational exposure and inability to discern CO symptoms, respectively. CO related mortality remained essentially unchanged in 2002 despite increased CO detector use.^{22,24,26} More than half of these cases (64%) occurred in homes with faulty furnaces, usually in the fall or winter months. Many clusters are associated with power failures during catastrophic weather, such as ice storms, blizzards, and hurricanes.^{22,23} With improved data collection, the CDC WONDER database reported 1944 deaths in the United States in 2010 due to the toxic effects of CO.²⁷

Just as important as mortality, are the greater number of survivors from CO poisoning. Despite increased awareness for CO poisoning, in 2004 to 2006, there were still an average of 20,636 nonfatal, unintentional, non-fire-related CO exposures treated annually in the United States.²⁶ More than 40% of cases occurred in the winter, with almost 75% occurring in residences. However, exclusion of intentional and fire related cases severely underestimates the extent of the problem. Based on firsthand hospital data, a minimum of 50,000 CO cases present to US Emergency Departments (EDs) each year, up to half resulting in hospitalization.^{80,91} More recent data using probable and suspected cases suggests that there were over 230,000 ED visits in 2007 alone that were unintentional and related to non-fire CO poisoning.⁹²

The bigger problem with CO poisoning may be the associated morbidity that survivors risk even after acute treatment. The most serious complication is persistent or delayed neurologic or neurocognitive sequelae, which occurs in up to 50% of patients with symptomatic acute poisonings.^{68,144,196} There is still no highly reliable method of predicting who will have a poor outcome, requiring the threshold for HBO therapy for CO poisoning and follow-up be particularly low.

Potential sources of CO abound in our society, often resulting in unintentional poisoning²⁶ (Table 125–1). Although CO is found naturally in the body as a byproduct of hemoglobin degradation by heme oxygenase found in the liver and spleen,⁴⁰ it is readily available for inhalation from the incomplete combustion of virtually any carbonaceous fuel. Alternatively, absorption—dermal, ingestion, or inhalation—of methylene chloride may result in CO toxicity after hepatic metabolism¹²⁸ (Chap. 108). Despite catalytic converters and other emission controls, more than 50% of unintentional CO deaths are still caused by motor vehicle exhaust.^{39,123} Occupants of motor vehicles are not the only victims of exhaust gases; CO poisoning is also reported in occupants of the beds of pickup trucks and on boats.^{21,79} Workers can become symptomatic from use of propane powered equipment indoors such as ice skating rink resurfacers²⁰ and forklifts.⁵⁵ For optimal performance, propane-powered forklifts are typically adjusted to produce no less than 10,000 ppm of CO in exhaust, but in fact average more than 30,000 ppm.⁵⁶ In an enclosed warehouse with poor ventilation, even with proper emission control, CO levels could exceed safe recommendations within an hour.

TABLE 125–1. Sources of Carbon Monoxide Implicated in Poisonings

Anesthetic absorbents
Banked blood
Boats
Camp stoves and lanterns
Charcoal grills
Coffee roasting
Formic acid (with strong acid)
Gasoline powered equipment (eg, generators, power washers)
Ice resurfacing machines
Methylene bromide
Methylene chloride
Natural gas combustion furnaces (water heaters, ranges and ovens)
Propane powered forklifts
Underground mine explosions
Wood pellet storage

In the past 10 years, non-vehicular sources of CO have increasingly accounted for the majority of unintentional poisonings.¹²³ Predominantly, these have involved the burning of charcoal, wood, or natural gas for heating and cooking.⁷⁶ Natural gas (methane or propane) burning furnaces for heating are often implicated, especially when the flue is blocked.^{83,84} Gas kitchen stoves are also an important source of CO in indigent populations with marginal heating systems.⁸⁴ In fact, the use of gas stoves for supplemental heat is predictive of CO poisoning in patients who present to the ED with headache and dizziness. During ice storms, blizzards, hurricanes, and other natural disasters, the indoor use of gasoline powered generators¹⁸⁹ and charcoal burning grills, the latter particularly in immigrant populations, has resulted in epidemic CO poisoning outbreaks.^{22,23,202}

Fires are another important source of CO exposure, contributing substantially to the approximate 5613 smoke inhalation deaths each year.³⁹ CO is considered to be the most common hazard to smoke inhalation victims.^{61,155} These cases are further compounded by the high incidence of hydrogen cyanide poisoning ([Chap. 126](#)).⁷¹

TOXICOKINETICS

CO is readily absorbed after inhalation. The Coburn-Forster-Kane (CFK) model allows the prediction of COHb levels based on exposure history.⁴¹ This model has been simplified to allow estimation of the equilibrium based on the ambient concentration of CO in ppm: $\text{COHb (\%)} = 100/[1 + (643/\text{ppm CO})]$.¹⁸¹ This assumes that the individual weighs 70 kg and is not anemic. With exponential uptake, it may take more than 4 hours for equilibrium to be attained. Therefore, within minutes of high CO exposures, the arterial COHb level may actually overshoot predicted estimates before equilibration.^{8,13} Endogenous production of CO is not factored in because its contribution to COHb is only 2%.

After it has been absorbed, CO is carried in the blood, primarily bound to hemoglobin. The Haldane ratio states that hemoglobin has approximately a 200 to 250 times greater affinity for CO than for oxygen. Therefore, CO is primarily confined to the blood compartment, but eventually up to 15% of total CO body content is taken up by tissue, primarily bound to myoglobin.⁴¹ Therefore, the dissolved CO level in the plasma may better reflect the ultimate potential for poisoning because it is available for diffusion into all tissue compartments, including the muscle and brain.¹⁰⁷

Elimination of CO, like absorption, from the blood can be modeled mathematically using the CFK model. The equation predicts a half-life of 252 minutes. In actual volunteer studies, means of 249 and 320 minutes breathing room air are reported.¹⁴¹ With 100% oxygen, these half-lives can be reduced significantly to means ranging 47 to 80 minutes in studies of volunteers who attain COHb levels of 10% to 12%.^{141,163} Patients poisoned with CO showed actual mean half-lives ranging from 74 to 131 minutes when treated with 100% oxygen.^{196,197}

Methylene chloride, a paint stripper, is another source of CO. It is readily absorbed through the skin or by ingestion or inhalation and is metabolized in the liver to CO.¹⁵⁸ Reaching peak COHb levels may take 8 hours or longer and may range from 10% to 50%.^{106,147} Because of ongoing production of CO, the apparent COHb half-life is prolonged to 13 hours in these patients.¹⁴⁵ COHb levels after methylene chloride exposure appear to be proportional to the concentration and duration of exposure.¹⁴⁵

PATHOPHYSIOLOGY

The most obvious deleterious effect of CO is binding to hemoglobin, rendering it incapable of delivering oxygen to the cells. Therefore, despite adequate partial pressures of oxygen in blood (PO_2), there is decreased arterial oxygen content. Further insult occurs because CO causes a leftward shift of the oxyhemoglobin dissociation curve, thus decreasing the offloading of oxygen from hemoglobin to tissue¹⁵⁰ (Fig. 22–2). This may result in part from a decrease in erythrocyte 2,3-bisphosphoglycerate (2,3-BPG) concentration. The net effect of all these processes is the decreased ability of oxygen to be delivered to tissue.

CO toxicity cannot be attributed solely to COHb-mediated hypoxia. Neither clinical effects nor the phenomena of delayed neurologic deficits can be completely predicted by the extent of binding between hemoglobin and CO.^{75,177} Furthermore, such a model fails to explain why even minimal levels of COHb (4%–5%) may result in cognitive impairment. An early study showed that dogs breathing 13% CO died within 1 hour and had COHb levels of 54% to 90%. However, exchange transfusion of this same blood into healthy dogs to reach similar COHb levels caused no untoward effects.⁶² Hemorrhaging the dogs to comparable degrees of anemia also produced no adverse effects. The appropriate conclusion was that inherent to CO toxicity is its delivery to target organs such as the brain and heart and that although COHb is easily measured; it rarely has a significant contribution to clinical toxicity. For CO to reach tissue, it had to be dissolved in the plasma rather than bound to hemoglobin.^{66,67}

CO interferes with cellular respiration by binding to mitochondrial cytochrome oxidase. Initial studies show that this binding is especially exaggerated under conditions of hypoxia and hypotension. In vitro rat models demonstrate that this oxidative stress causes mitochondrial damage with protein oxidation and lipid peroxidation, particularly in the hippocampus and corpus striatum.¹⁶⁴ In vivo models reveal that CO poisoning causes cell loss in the frontal cortex, which is associated with decrements in learning and memory.¹⁴² Although no comparable brain studies exist in humans, the peripheral lymphocytes and monocytes of CO-poisoned patients show cytochrome oxidase inhibition accompanied by increased lipid peroxidation.^{59,118} In a small clinical series of CO-poisoned patients, normalization of this cytochrome activity lagged behind and seemed to agree better with symptom severity than COHb levels.¹¹⁹

Inactivation of cytochrome oxidase may be only an initial part of the cascade of inflammatory events that results in ischemic reperfusion injury to the brain after CO poisoning (Fig. A38–1). During recovery from the initial poisoning, white blood cells are attracted to and adhere to the damaged brain microvasculature.^{169,170,171} This attraction may be partly attributable to endothelial changes from initial cytochrome oxidase dysfunction, mediated primarily through the free radical nitric oxide (NO).^{169,175} CO displaces NO from platelets that in turn form peroxynitrites, which are even stronger inactivators of cytochrome oxidase.¹⁷⁵ Multiple animal studies demonstrate that NO is ultimately responsible for much of the endothelial damage from CO and that NO synthase inhibitors can prevent toxicity.^{174,175} The NO formation promotes platelet–neutrophil aggregates that in turn lead to neutrophil adhesion to the brain microvasculature.¹⁷⁰ Myelin peroxidase activation in the area may further promote neutrophil adhesion with degranulation and release of proteases that convert xanthine dehydrogenase to xanthine oxidase, an enzyme that promotes formation of oxygen free radicals.¹⁶⁸ The end result of this process is delayed lipid peroxidation of the neurons, and the extent of destruction may be correlated with decrements in learning in rodents.¹⁶⁸ Rats depleted of xanthine oxidase through a tungsten modified diet show no changes in myelin basic protein and cognitive function after CO poisoning.⁸²

Simultaneously, with all this perivascular oxidative stress in the brain, there is activation of excitatory amino acids, which ultimately may be responsible for the subsequent neuronal cell loss.¹⁷⁵ In fact, in rat brains, glutamate concentrations increase after CO poisoning. Glutamate is an excitatory amino acid that can bind at N-methyl-D-aspartate (NMDA) receptors and cause intracellular calcium release, resulting in delayed neuronal cell death (Chap. 14). Blockade of NMDA receptors may prevent the neuronal death and learning deficits that accompany serious CO poisoning in mice.⁹³ Increases in the glutamate concentrations in rat brain in the first hour after severe CO poisoning are followed by a later increase in hydroxyl radicals.¹⁴² Ultimately, at 1 to 3 weeks, the animals show histologic evidence of both neuronal necrosis and apoptosis in the frontal cortex, globus pallidus, and cerebellum that are accompanied by deficits in learning and memory.

CO neuronal cell death may be caused by apoptosis, which has been confirmed in various models. In bovine pulmonary artery cells, CO exposure is accompanied by activation of caspase-1, a protease implicated in delayed cell death.¹⁷³ Confirmatory evidence was provided in the same study because both caspase-1 and NO synthase inhibitors blocked apoptosis. The end result of all these cellular processes is brain injury, particularly in the basal ganglia and hippocampus.¹⁹² In some studies this is accompanied by learning impairment.¹⁴² Thus, animal models correlate well with what ultimately occurs in victims of serious CO poisoning, namely, persistent or delayed deficits in learning and memory associated with structural changes in the brain.

Myoglobin, another heme protein, binds CO with an affinity about 60 times greater than it binds oxygen.⁴² About 10% to 15% of the total body store of CO is extravascular, primarily binding to myoglobin.^{13,41} A dog model demonstrates that this binding is enhanced under hypoxic conditions.⁴² This binding may partially explain the myocardial impairment that occurs in both animal studies and low-level exposures in patients with ischemic heart disease. The combination of COHb formation, which decreases oxygen-carrying capacity, and reduced myoglobin in the heart, which decreases oxygen

extraction, may explain the preterminal dysrhythmias that occur in animals.

Several studies suggest that CO effects on the cardiovascular system are necessary for ischemic reperfusion injury of the brain. Hypotension is an essential component and results from a combination of myocardial depression and vasodilation. CO, perhaps because of its similarity to NO, activates guanylate cyclase, which in turn relaxes vascular smooth muscle. Also, CO may further displace NO from platelets, resulting in additional vasodilation.¹⁷⁴ These factors contribute to the hypotension that occurs in animal experiments with exposure to high concentrations of CO.⁶² Such an episode of hypotension may present clinically as syncope, and this finding portends a worse clinical outcome.³⁴ In rhesus monkeys, cerebral white matter lesions correlate better with decreases in blood pressure than with COHb level.⁶⁵ Lipid peroxidation of the brain in rats develops an hour after a CO exposure that has produced syncope and hypotension.¹⁶⁷ This delay is comparable to the time that is necessary to produce mitochondrial destruction from oxidative stress in rats exposed to CO. In a feline model, central nervous system (CNS) damage from CO can be reproduced only when hypoxia is accompanied by an interval of ischemia, confirming the ischemic-reperfusion model.¹³²

Endogenous CO behaves like NO, binding to guanylate cyclase and thereby increasing cGMP concentrations.⁹⁴ Although low endogenous concentrations are physiologic, excessive concentrations of CO from exogenous sources may be problematic because CO persists much longer than NO. CO appears to be a neuronal messenger by virtue of the fact that as a gas, it can diffuse and signal adjacent cells.¹¹²

CLINICAL MANIFESTATIONS

Acute Exposure

The earliest symptoms associated with CO poisoning are often nonspecific and readily confused with other illnesses, typically a viral syndrome¹⁹³ (Table 125–2). The initial symptom reported by volunteers within 4 hours of exposure to 200 ppm CO (producing COHb levels of 15%–20%) is headache; shorter exposures at 500 ppm also produce nausea.¹⁶⁰ The incidence of CO poisoning in symptomatic patients presenting to EDs in the winter with an influenzalike illness ranges from 3% to 24% in some series.^{51,84} The typical presenting complaints include headache, dizziness, and nausea, and the most frequent exposures occur during the winter, explaining why influenza is the most common misdiagnosis.⁵¹ The most common symptom, headache, is usually described as dull, frontal, and continuous. CO poisoning is also frequently misdiagnosed as food poisoning, gastroenteritis, and even colic in infants. Similar to adults, children tend to develop nonspecific symptoms, complicating diagnosis.

TABLE 125–2. Clinical Manifestations of CO Poisoning

Ataxia	Myocardial ischemia
Cardiac dysrhythmias	Nausea
Chest pain	Syncope
Confusion	Tachypnea
Dizziness	Visual blurring
Dyspnea	Vomiting
Headache	Weakness

Continued exposure to CO may lead to symptoms attributable to oxygen deficiency in the heart. Low-level exposures, leading to COHb levels of 2% to 4%, in volunteers with stable angina results in decreased exercise tolerance as well as signs and symptoms of myocardial ischemia.² At higher levels (COHb 6%), there is a greater frequency of premature ventricular contractions during exercise. Myocardial infarction and dysrhythmias are described in victims of CO poisoning, and acute mortality from CO is usually a result of ventricular dysrhythmias.^{1,2} Prolonged exposure to CO or high COHb levels are associated with temporary myocardial stunning, lasting usually less than 24 hours and reflected by a decrease in left ventricular ejection fraction (LVEF).⁹⁵ This stunning is reflected by a decrease in LVEF and is correlated with increased β -type natriuretic peptide. Troponin may also be elevated in the absence of any coronary artery disease or even ECG or ECHO changes.^{28,46} These patients have an increased propensity for cardiac mortality, with almost one-third dying within 8 years after serious CO poisoning.⁸⁵

The CNS is the organ system that is most sensitive to CO poisoning. Acutely, otherwise healthy patients may manifest headache, dizziness, and ataxia at COHb levels as low as 15% to 20%; with higher levels or longer exposures causing syncope, seizures, or coma.¹⁹³ Patients may present with focal neurologic symptoms suggestive of a cerebrovascular accident. The electroencephalogram (EEG) may show diffuse frontal slow-wave activity. Within a day of exposures that result in coma, computed tomography (CT) and magnetic resonance imaging (MRI) can show decreased density in the

central white matter and globus pallidus (Fig. 125–1).¹⁰⁸ Autopsies show involvement of other areas, including the cerebral cortex, hippocampus, cerebellum, and substantia nigra.¹⁰⁴

FIGURE 125–1. Computed tomography of the brain showing bilateral lesions of the globus pallidus (arrows) in a patient with poor recovery from severe carbon monoxide poisoning. (Used with permission of The New York City Poison Center Fellowship in Medical Toxicology.)

Metabolic changes may reflect CO's toxic effects better than any particular COHb level. Patients with mild CO poisoning may develop respiratory alkalosis in an attempt to compensate for the reduction in oxygen-carrying capacity and delivery. More substantial exposures result in metabolic acidosis with lactate production that accompanies tissue hypoxia.¹⁵⁷ Even in the absence of hypotension, lactate was an independent predictor of worse mental status and inpatient complications.¹²² The importance of metabolic acidosis was highlighted in a retrospective series of 48 CO-poisoned patients, in which hydrogen ion concentration was a better predictor of poor recovery during initial hospitalization than was COHb level.¹⁸⁶

Although the brain and heart are the most sensitive, other organs may also manifest the effects of CO poisoning. One-fifth to one-third of patients with severe CO poisoning—those who required endotracheal intubation—develop pulmonary edema.⁶⁹ This can be due to cardiac depression directly from CO and ARDS from associated smoke inhalation.^{71,95,155} This does not appear to be a direct effect of CO on lung tissue because sheep with prolonged exposure to CO, resulting in COHb levels greater than 50%, showed no anatomic or physiologic changes in lung function.¹⁵⁴ Although myonecrosis and even compartment syndromes occur, patients rarely develop acute kidney injury (AKI). Retinal hemorrhages may develop with exposures greater than 12 hours.⁹⁶ Cherry-red skin coloration occurs only after excessive exposure (2%–3% of cases referred to one hyperbaric center) and may represent a combination of CO-induced vasodilation, concomitant tissue ischemia, and failure to extract oxygen from arterial blood.¹⁴⁸ Another classic but uncommon phenomenon is the development of cutaneous bullae after severe exposures. These bullae are thought to be caused by a combination of pressure necrosis and possibly direct CO effects in the epidermis.

NEUROCOGNITIVE SEQUELAE

The persistent or delayed effects of CO poisoning are varied and include dementia, amnestic syndromes, psychosis, parkinsonism, paralysis, chorea, cortical blindness, apraxia and agnosia, peripheral neuropathy, and incontinence.¹⁰⁵ If not diagnosed at initial poisoning, neurologic deterioration can be delayed and preceded by a lucid period of 2 to 40 days after the initial poisoning.³⁴ In patients admitted to an intensive care unit for severe CO poisoning and treated with 100% oxygen, 14% of survivors had permanent neurologic impairment.¹⁰⁰ In a Korean series of 2360 CO-poisoned patients, 3% continued to show memory failure or parkinsonian features one year after exposure.³⁴ Another series of 63 seriously

poisoned patients showed memory impairment in 43% and deterioration of personality in 33% at 3-year follow-up.¹⁵⁷ Children also develop behavioral and educational difficulties after severe poisoning.¹⁰³ However, patients older than 30 years of age appear to be more susceptible to the development of delayed sequelae.^{34,198} Most cases of delayed neurocognitive sequelae are associated with loss of consciousness in the acute phase of toxicity.³⁴

Neurocognitive sequelae probably involve lesions of the cerebral white matter.⁶³ Weeks after exposure, autopsies show necrosis of the white matter, globus pallidus, cerebellum, and hippocampus. MRI studies confirm the damage to the white matter and hippocampus.^{58,108,193} Animal studies show that having a markedly elevated COHb level alone cannot cause similar white matter lesions but that there must also be an episode of hypotension.^{65,132} The fact that the areas permanently damaged in serious CO poisoning cases are the areas with the poorest vascular supply in the brain is consistent with these findings.

CHRONIC EXPOSURE

Often, patients complain of persistent headaches and cognitive problems after long-term exposure to low concentrations of CO. Unfortunately, to date, there have been no controlled studies demonstrating that in the absence of a severe acute poisoning episode, this type of exposure results in any long-term sequelae. Warehouse workers who are chronically exposed to CO from propane combustion have intermittent problems with headache, nausea, and lightheadedness.⁵⁵ Fortunately, unless there has been an episode of severe poisoning with acute deterioration, most workers go on to have resolution of their symptoms.⁵⁶ One series of chronic CO poisoning demonstrates a high incidence of headache and memory complaints along with motor slowing and memory problems on neuropsychologic testing.¹²⁵ Although many of the objective deficits improved with elimination of the exposure and HBO treatment, many continued to have posttraumatic stress and conversion disorders. Although it is unclear that chronic exposure to low concentrations of CO can cause permanent damage, health care providers still should be vigilant for symptomatic individuals to prevent continued or catastrophic outcomes.

DIAGNOSTIC TESTING

The most useful diagnostic test obtainable in a suspected CO poisoning is a COHb level. Normal levels of COHb range from 0% to 5%. Levels at the high end of this range occur in neonates and patients with hemolytic anemia because CO is a natural byproduct of the breakdown of protoporphyrin to bilirubin.³³ Of note, in blood samples from neonates, falsely high COHb levels up to 8% can occur due to interference of fetal hemoglobin with spectroscopy.¹⁹¹ COHb levels average 6% in one-pack-per-day smokers but may range as high as 10%.¹⁵⁹ Although high COHb levels confirm exposure to CO, particular levels are not necessarily predictive of symptoms or outcome.^{75,140}

The usual method for measuring COHb is with a cooximeter, a device that spectrophotometrically reads the percentage of total hemoglobin saturated with CO. Traditionally, arterial blood was used for this determination; however, venous blood levels are accurate as there is little CO extraction from hemoglobin across the capillary bed.¹⁸⁵ Refrigerated heparinized samples yield accurate COHb levels for months and at room temperature for 28 days, making retrospective clinical and postmortem evaluations reliable.^{73,102}

Bedside tests using ammonia or sodium hydroxide are unable to differentiate reliably various levels of COHb versus control subjects.¹³⁴ Because of the similarities in extinction coefficients, COHb is misinterpreted as oxyhemoglobin on most types of pulse oximetry (Chap. 29).⁷ Thus, the pulse oximetry reading is usually normal in the setting of even severe CO poisoning.⁷² Some newer pulse oximeters, called pulse cooximeters, have the ability to measure COHb noninvasively.⁵ A study in 10 healthy volunteers who inhaled CO at 500 ppm until they reached a peak COHb level of 15% found good agreement between pulse cooximetry and cooximetry.⁶ Early models of a commercial bedside pulse cooximeter showed very poor agreement, mischaracterizing half the patients with levels over 15% as lower.¹⁸⁵ Subsequently, another large cohort of ED patients, using a later model of the same device, found that it measured COHb well, with a bias of 3% and precision of 3.3%.¹⁴⁹ Because it tends to overestimate COHb, the authors recommend a normal upper limit of 6.6% as triggering intervention. Because the pulse cooximeter is noninvasive, it may be useful in screening ED patients for occult CO poisoning who present with nonspecific symptoms.³¹ In addition, it may be used in the field for screening fire victims, patients with potential CO exposure, and rescuers.

Breath-sampling methods may be used for screening patients.^{43,45,53} A cutoff of 53 ppm in patients breathing air and 43 ppm in those breathing oxygen has an approximate reliability of approximately 80% in predicting COHb levels above 10%.⁵⁷ Breath sampling for CO has been advocated as a quick screening device for detecting recent exposure to CO in ED patients.

Some clinical laboratories measure CO directly in blood samples rather than COHb. This technique involves assaying

CO directly with infrared spectrophotometry after it is extracted from the blood sample with a manometer. Based on calculations rather than true experimental data, the assumption has been made that for a patient with a normal hemoglobin, a CO level of 1 mmol/L corresponds to an 11% COHb concentration. A simpler method to measure serum CO content is to add a known solution of hemoglobin followed by sodium dithionite to form COHb. The resulting COHb is measured spectrophotometrically with the assumption that 1 mole of hemoglobin binds 4 moles of CO. Interestingly, in one study, serum CO ranged from 0.14 to 0.6 mg/L but was the same in smokers (average, 4.6% COHb) and nonsmokers (average, 1% COHb).²⁰⁰ At this time, further research is required to determine the clinical importance of serum CO content.

Additional laboratory tests may be useful in severe poisoning cases. An arterial or venous blood gas analysis will confirm the presence of metabolic acidosis, and a measurement of serum lactate concentration can be performed simultaneously. Metabolic acidosis with elevated lactate concentration may serve as a more reliable index of severity than a measurement of the COHb concentration.¹⁵⁷ Unfortunately, arterial pH does not correlate well with either initial neurologic examination or the COHb level, making it a poor criterion for deciding the need for HBO treatment.¹²⁴ Specificity of lactate may also be low in smoke inhalation victims, where it may indicate concomitant cyanide poisoning (Chap. 126).

Cardiac monitoring and a 12-lead electrocardiography (ECG) are essential to identify ischemia or dysrhythmias in symptomatic patients with preexisting coronary artery disease or severe exposure. Mild elevations of creatine phosphokinase are common (ranging 20–1315 IU/L in one series of 65 cases), usually because of rhabdomyolysis rather than cardiac sources.¹⁵³ However, because CO may cause myocardial infarction in the presence of normal coronaries,⁹⁵ it is not surprising to see nonspecific increases in troponin concentrations, which may reflect diffuse cardiac myonecrosis rather than focal coronary artery disease.²⁹ Congestive heart failure or hypotension can be evaluated with a β -type natriuretic peptide or echocardiography (or both), looking for evidence of myocardial stunning.⁹⁵ Because of the potential for increased cardiovascular mortality,⁸⁵ patients with ECG changes or elevated cardiac enzymes may benefit from further cardiac testing, a stress test, or angiography.

The problem with using COHb levels to base treatment is that there is a wide variation in clinical manifestations across patients with identical COHb levels. Furthermore, particular COHb levels are not predictive of symptoms or final outcome.^{114,131,157} In a large prospective study of CO poisoning, COHb levels did not correlate with loss of consciousness and were not predictive of delayed neurologic sequelae.¹⁴⁴ Admission COHb levels are inaccurate predictors of peak levels, and the use of nomograms to extrapolate to earlier levels has not been validated. Their credibility is also suspect because of the great variability in COHb half-lives and differences in treatment with oxygen.

Because of the inherent unreliability of COHb levels in predicting outcome, researchers are searching for other surrogate markers. Rats have early increases in glutathione released from erythrocytes, a potential marker for CO oxidative stress that could ultimately lead to brain injury.¹⁷⁶ Another promising marker is serum S100B, a structural protein in astroglia that is released from the brain after hypoxic stress. A series of 38 consecutive patients poisoned with CO showed that those who presented with normal neurologic findings and no loss of consciousness had normal S100B concentrations.¹⁵ Patients who presented with loss of consciousness and neurologic deficits all had elevated concentrations. CO-poisoned rats treated with HBO did not develop elevated S100B concentrations unlike those treated with ambient oxygen therapy.¹⁴ Although markers used for cerebral injury, specifically S100B and neuron-specific enolase, do rise after CO poisoning, they have not been shown to be predictive of final outcome.^{17,146} Levels at the target organ, the brain, show that S100B in the cerebrospinal fluid predicted extreme neurological sequelae, that is, persistent vegetative state, only.⁹⁰ A recent pilot study concluded that almost 100 different plasma proteins—cytokines, chemokines, and other biomarkers—increase after CO poisoning in patients; their significance awaits more definitive studies.¹⁷²

NEUROPSYCHOLOGIC TESTING

The extent of neurologic insult from CO can be assessed with a variety of tests. The most basic is documentation of the normal neurologic examination with a quick mini mental status examination. A more sensitive indicator of the acute effects of CO on cortical function is a detailed neuropsychologic test battery developed specifically for CO patients.¹¹⁷ The advantages of such testing, which usually takes about 30 minutes, are that it can reliably distinguish 79% of the time between CO-poisoned patients and control subjects, and it shows improvement with appropriate HBO treatment.¹¹⁷ Unfortunately, such testing shows a sensitivity of only 77% and specificity of 80% for CO poisoning. There may be practice effects as well if repeated testing is performed. Another study suggested that the degree of impairment CO patients had on a test of short-term rote and context-aided verbal memory correlated well with the number of HBO treatments needed.¹¹⁵ The biggest problem with such neuropsychiatric testing is that it is unclear if deficits in the test during the acute CO poisoning phase are at all predictive of the development of neurologic sequelae and therefore the necessity of HBO treatment.

NEUROIMAGING

Acute changes on CT scans of the brain occur within 12 hours of CO exposure that resulted in loss of consciousness.^{108,120} Symmetric low-density areas in the region of the globus pallidus, putamen, and caudate nuclei are frequently noted.⁸⁸ Changes in the globus pallidus and subcortical white matter early within the first day after poisoning are associated with poor outcomes¹³⁶ (Fig. 125–1). Alternatively, in one series of 18 patients, a negative CT within a week of admission was associated with favorable outcome.¹⁸² The use of contrast may enhance early isodense changes not visible on initial CT scan²⁰⁶ but is not routinely performed.

MRI appears to be superior in detecting basal ganglia lesions after CO poisoning.¹⁰⁸ One study found a much higher incidence of periventricular white matter changes on MRIs done within the first day after exposure. However, such changes had no correlation with COHb level or cognitive sequelae.¹³⁶ These periventricular changes are more common and probably more sensitive than globus pallidus lesions. Globus pallidus lesions were present on MRI in only one patient (1.4%) in a prospective study of CO-poisoned patients, half of whom had loss of consciousness.⁸⁸ Diffusion-weighted MRI may have more promise in detecting changes in subcortical white matter within hours of serious CO poisoning.¹⁶⁵ Regardless, neuroimaging usually does not influence patient management and can be reserved for patients who show poor response or have an equivocal diagnosis.

The most promising area of neuroimaging after CO poisoning is in assessing regional cerebral perfusion.^{37,135} Single-photon emission CT (SPECT) gauges regional blood flow noninvasively using an iodine or technetium tracer. In one series of 13 patients with delayed neurologic sequelae, all cases showed patchy hypoperfusion throughout the cerebral cortex within 11 days of poisoning.³⁵ These changes in perfusion may occur as early as one day after poisoning and primarily involve watershed regions such as the temporoparietooccipital area.⁴⁹ Perfusion defects on SPECT scanning appear to be associated with neuropsychological impairment months after serious CO poisoning.⁵⁸ Unfortunately, because of the scant availability of the procedure and the lack of comprehensive studies, SPECT scanning is not the definitive tool at this time for determining prognosis or need for HBO. In addition, when imaging patients 1 to 2 years post poisoning, it appears that T2 weighted imaging on MRI is more sensitive than SPECT scanning.³²

Positron emission tomography (PET) can also be used to evaluate regional blood flow as well as oxygen metabolism in the brain after CO exposure. In one series of severely CO-poisoned patients, PET examination after HBO treatment showed increased oxygen extraction and decreased blood flow in the frontal and temporal cortices.⁴⁷ Of note, patients with permanent deficits persisted in showing these abnormalities on PET scanning. One delayed PET study demonstrated that increases in dopamine D₂ receptor binding in the caudate and putamen after CO poisoning were improved with bromocriptine, at which time neuropsychiatric symptoms resolved.²⁰⁵ Although PET scanning cannot be used to predict outcome, abnormalities that persist on the scan may be indicative of patients with permanent neurologic sequelae.

To complement perfusion studies, EEG mapping has also been performed on CO-poisoned patients. Although initial studies demonstrate that many patients have regional EEG abnormalities after poisoning, it is unknown if these are predictive of persistent or delayed neurologic problems. EEG mapping may be discrepant relative to SPECT scanning because EEG preferentially demonstrates subcortical lesions.

MANAGEMENT

The mainstay of treatment is initial attention to the airway. One hundred percent oxygen should be provided as soon as possible by either non-rebreather face mask or endotracheal tube. Although concerns have been raised regarding toxicity from excess oxygen, patients poisoned with CO can still have cellular hypoxia in spite of normal oxygen saturation.^{12,72} It is important to remember that a non-rebreathing mask only delivers 70% to 90% oxygen; a positive pressure mask or an endotracheal tube is necessary to achieve higher oxygen concentrations. The immediate effect of oxygen is to enhance the dissociation of COHb.¹⁵⁰ In volunteers, the half-life of COHb is reduced from a mean of 5 hours (range, 2–7 hours) when breathing room air (21% oxygen) to approximately one hour (range, 36–137 minutes) when breathing 100% oxygen at normal atmospheric pressure.¹⁴¹ Actual poisonings show a range in half-lives of 36 to 137 minutes (mean, 85 minutes) when breathing 100% oxygen; the longer elimination half-lives appear to be most often associated with long, low-level exposures.^{126,197} With oxygenation and intensive care treatment, hospital mortality rates for serious exposures range from 1% to 30%. The duration of treatment is unclear, with a valid end point being the resolution of symptoms, usually accompanied by a COHb below 5%.

Cardiac monitoring and intravenous (IV) access are necessary in any patient with systemic toxicity from CO poisoning. Hypotension can initially be treated with IV fluids; inotropes may also be necessary to treat myocardial depression. An evaluation for cardiac ischemia, including ECG and cardiac markers, should be considered in symptomatic patients at risk. Standard advanced cardiac life support protocols can be followed for the treatment of patients with life-threatening dysrhythmias. Patients with a depressed mental status should have a rapid blood glucose checked. Animal studies of CO

poisoning suggest that hypoglycemia can be deleterious.¹³⁸ Correction of any acidemia with bicarbonate is controversial and may result in further cellular injury secondary to a left shift of the oxyhemoglobin dissociation curve, so it is not recommended unless the acidemia is profound and persistent.

HYPERBARIC OXYGEN

HBO therapy appears to be the treatment of choice for patients with significant CO exposures.¹⁷⁸ But the most obvious effect, may not be the most important. One hundred percent oxygen at ambient pressure reduces the half-life of COHb from about 320 minutes to 85 minutes; at 2.5 atmospheres absolute (ATA), it is reduced to 20 minutes.^{141,197} Actual CO-poisoned victims treated with HBO have half-lives ranging from 4 to 86 minutes.¹²⁶ HBO also increases the amount of dissolved oxygen by about 10 times, which is sufficient alone to supply metabolic needs in the absence of hemoglobin (Chap. 29).¹⁰ This is rarely an important clinical issue because most patients have already been stabilized and have appreciably decreased COHb with ambient oxygen alone before arrangements can be made for an HBO treatment.

Therefore, HBO is more than just a modality to clear COHb more quickly than ambient oxygen (Antidotes in Depth: A38). More importantly, in rats after loss of consciousness from CO exposure, hyperbaric, but not normobaric, oxygen therapy prevents brain lipid peroxidation.¹⁶⁶ HBO appears to prevent ischemic reperfusion injury by a variety of mechanisms. First, in animal models, HBO accelerates regeneration of inactivated cytochrome oxidase, which may be the initiating site for CO neuronal damage.¹² Unlike 100% oxygen at room pressure, in clinical trials, HBO was much more effective at restoring mitochondrial function within peripheral white blood cells in CO poisoned patients.⁵⁹ Second, HBO also prevents β -integrin mediated neutrophil adhesion to brain microvascular endothelium, a process essential for amplification of CNS damage from CO.¹⁷⁸ This may explain why HBO, but not 100% oxygen at atmospheric pressure, prevented delayed deficits in a learning and memory maze model.¹⁷⁰

Clinical studies of the effectiveness of HBO in preventing neurologic damage from CO are not as convincing as basic science studies would suggest. In uncontrolled human clinical series, the incidence of persistent neuropsychiatric symptoms, including memory impairment, ranged from 12% to 43% in patients treated with 100% oxygen and was as low as 0% to 4% in patients treated with HBO.^{69,114,127,131}

More recently, several controlled clinical trials have evaluated the efficacy of HBO in CO poisoning (Table 125–3). The first randomized study of CO poisoning included more than 300 patients and failed to show a benefit from HBO in patients who had no initial loss of consciousness.¹⁴⁴ Unfortunately, seriously ill patients were not randomized to surface pressure oxygen; they received either one or three treatments of HBO. Flaws in the study included significant delays to treatment and the use of suboptimal pressure of 2.0 ATA. A smaller (n = 60) controlled study avoided some of these flaws and showed that HBO decreased delayed neurologic sequelae at 3 to 4 weeks from 23% to 0% in CO-poisoned patients who presented without loss of consciousness.¹⁸⁰ However, patients with syncope, a marker of serious poisoning, were excluded. A very small study (n = 26) of patients presenting with Glasgow Coma Scores (GCS) above 12 after CO poisoning included almost half with loss of consciousness.⁵² Randomization to HBO versus 100% normobaric oxygen resulted in decreased EEG abnormalities and less reduction in blood flow reactivity to acetazolamide at 3 weeks. Unfortunately, all of these studies failed to definitively study all CO-poisoned patients, including those with syncope or coma.

TABLE 125–3. Unfavorable Cognitive Outcome at 4 to 6 Weeks After Exposure to Carbon Monoxide in Randomized Clinical Trials of Hyperbaric Oxygen

Study	Design	Max HBO Pressure	Time to Treatment	Syncope (%)	Suicide (%)	Treatment	Control	Odds Ratio (95% CI)
Mathieu ¹⁴⁰	HBO 90 minutes vs. 12 hour NBO	2.5 ATA	<12 hours	N/A	N/A	69/299	73/276	0.83(0.57–1.22)
Raphael ¹⁴¹	HBO 2 hours vs. 6 hour NBO	2.0 ATA	Mean, 7.1 hours	0	N/A	51/159	50/148	0.93(0.57–1.49)
Thom ¹⁴²	HBO 2 hours vs. 100% NBO until asymptomatic	2.8 ATA	Mean, 2.0 hours	0	N/A	0/30	7/30	0.05(0.00–0.95)
Scheinkestel ¹⁵²	HBO 1 hour vs. NBO 100 minutes	2.8 ATA	Mean, 7.1 hours	53%	69%	30/48	25/40	1.00(0.42–2.38)
Weaver ¹⁴³	HBO 2 hours (x3) vs. NBO 2 hours (x1)	3.0 ATA	Mean, 5.6 hours	53%	31%	19/76	35/76	0.39(0.20–0.78)
Annan ⁴	HBO 2 hours vs. NBO 6 hours	2.0 ATA	< 6 hours	97%	0%	33/93	29/86	1.08 (0.58–2.00)

Data from Buckley N, Juurlink D, Ibister G, et al: Hyperbaric oxygen for carbon monoxide poisoning. *Cochrane Database Syst Rev*. 2011;CD002041 and Tomaszewski C. The case for the use of hyperbaric oxygen in carbon monoxide poisoning. In: Penney DG, ed. *Carbon Monoxide Poisoning*. New York: CRC Press; 2008:375–390.

ATA = atmospheres absolute; CI = confidence interval; HBO = hyperbaric oxygen; N/A = not applicable; NBO = normobaric oxygen.

The first randomized trial to directly address the issue of HBO efficacy in seriously CO-poisoned patients evaluated 191 CO-poisoned patients referred for HBO treatment.¹⁵² Patients were randomized to a minimum of three daily treatments of HBO (2.8 ATA for 60 minutes) or 100% oxygen at 1.0 ATA for 3 days. Although the HBO group had a higher incidence of persistent neurologic sequelae at one month, there was no significant difference between the two groups; more than two-thirds of each group had persistent problems. This study, although the largest controlled, randomized study to date, suffered from several flaws. Fewer than half of the patients had follow-up at one month. Disproportionate numbers of suicide cases (about two-thirds) and drug toxicity (44%), with accompanying neuropsychologic defects, could have confounded any beneficial effect from HBO. Finally, HBO treatment was delayed for 6 hours, making it much less likely to be effective.^{69,144}

A more recent randomized, double-blind, placebo-controlled study identified a beneficial effect of HBO in CO-poisoned patients.¹⁹⁶ Most of these patients were ill, with a mean initial COHb level of 25% and a 50% incidence of loss of consciousness. Patients were all treated within a 24-hour window after exposure, but the success of the study might be partially attributable to the rapid mean time to treatment of less than 2 hours. Patients received HBO three times at intervals of 6 to 12 hours, each at 2.0 ATA, except for the first hour of the first treatment, which was at 3.0 ATA. Control patients received sham treatments in the HBO chamber with 100% oxygen at 1.0 ATA. At 6 weeks, the HBO group had a 24% incidence of cognitive sequelae versus 46% in the control group. Based on these data, the number of patients needed to treat to prevent one case of cognitive impairment is only five. Critics of this study point out that the neuropsychiatric tests were not significantly different between the groups except for digit span and trail making, and there was no difference in activities of daily living. However, untreated patients had increased self-reported memory problems at 6 weeks (28% vs. 51%), and the beneficial effect on cognitive sequelae lasted well into 12 months.

A more recent study of 179 patients with transient loss of consciousness after CO poisoning showed no benefit from a single HBO treatment.⁴ Neurological recovery at one month was approximately 60% regardless of HBO or normobaric oxygen. However, the study was done only at 2.0 ATA, which is below the customary initial dose for CO in positive studies. In addition, over 20% of patients were lost to follow-up.

Based on the strong animal and basic science experience, the positive human studies mentioned above, and few adverse effects, it is not surprising that the Underwater and Hyperbaric Medical Society (UHMS) recommends HBO for all CO patients with signs of serious toxicity.¹⁹⁵ With the low risk of this procedure,^{151,156} almost 1500 patients are treated with HBO for CO poisoning in the United States each year.⁷² Therefore, HBO has become the standard of care for serious CO poisoning, even though there is substantial disagreement in the interpretation of the existing evidence.^{83,109,201}

Indications for Hyperbaric Oxygen Therapy. Although specific indications for HBO after acute CO poisoning are listed (Table 125–4), they have not been prospectively evaluated. The patients most likely to benefit are those most at risk for persistent or delayed neurologic sequelae, such as those presenting in coma or with a history of syncope.¹⁹⁸ These may be clinical markers for the episode of hypotension that are necessary for causing neuronal damage from CO-induced ischemic–reperfusion injury in animal models^{65,133} However, syncope is neither particularly sensitive nor specific marker for cognitive sequelae. Patients with long exposures, or “soaking” periods, typically longer than 6 hours, are also at greater risk for neurologic sequelae.¹¹ The presence of a significant metabolic acidosis may be a surrogate marker.^{157,186} Patients

who present with decreased level of consciousness, a GCS <9 in one series, had an odds ratio of 7.0 for development of neurological sequelae¹⁴⁰ Some authors advocate ongoing myocardial ischemia as an indication for HBO; however, in our experience, these patients usually already meet neurologic criteria for treatment, such as loss of consciousness or ongoing mental status changes. Isolated cardiac ischemia, more importantly, deserves immediate proven myocardial salvaging therapy rather than delayed treatment with an unproven therapy such as HBO

TABLE 125–4. Suggested Indications for Hyperbaric Oxygen^a

Syncope (loss of consciousness)
Coma
Seizure
Altered mental status (GCS<15) or confusion
Carboxyhemoglobin >25%
Abnormal cerebellar function
Age = 36 years
Prolonged CO exposure (=24 hours)
Fetal distress in pregnancy

^aPatients with these risk factors for cognitive sequelae have the highest potential to benefit from HBO treatment. GCS = Glasgow Coma Score.

Some authors advocate treating all patients with COHb levels of 40% or greater with HBO. Many HBO centers arbitrarily use a more conservative level of 25% as an indication for HBO.⁷⁸ More important than actual level are patient history and examination. Further analysis of data from the most recent controlled trial demonstrates that in patients not treated with HBO, there were no reliable factors (COHb level, loss of consciousness, or base excess) for predicting who progressed to cognitive sequelae.¹⁹⁸ This recent multivariate analysis showed that of all factors (loss of consciousness, age, exposure time, and COHb levels) only age of 36 years or older and CO exposure duration of 24 hours or longer predicted cognitive dysfunction at 6 week follow-up. More problematic is the incidence of cognitive sequelae in patients without those risk factors: 32% in those younger than age 36 years and 36% in those with less than 24 hours of exposure. In conclusion, it appears that there are no reliable predictors for screening out patients who will do well and not develop cognitive sequelae, and therefore can avoid HBO treatment with mild CO poisoning.

Multiple studies have looked for serum markers after acute CO poisoning that would predict neurological sequelae. COHb, although confirming exposure, does not correlate with future outcome, let alone acute symptoms.^{75,198} Multiple serum markers, including cytokines, do increase after CO poisoning, but their predictive accuracy is unclear.¹⁷² Although impaired mitochondrial cytochrome function and elevated lipid peroxidation are seen in peripheral lymphocytes and monocytes after clinical CO poisoning, they only confirm CO exposure and are too nonspecific to use as predictors of neurological sequelae.⁵⁹

Therefore, at this time, it is prudent to refer for HBO treatment those patients with the most serious neurologic symptoms, regardless of their COHb level. Such symptoms include coma, seizures, focal neurologic deficits, altered mental status (GCS <15), and although controversial, loss of consciousness. Patients who have had cardiac arrest from CO poisoning and had the return of spontaneous circulation may be poor candidates for HBO therapy because all these cases have been fatal.⁸¹ In fact, such deaths from CO poisoning are no contraindication to organ donation.

Excluding patients from HBO with milder symptoms after CO poisoning may be problematic because even they are susceptible to neurocognitive sequelae. One series of 55 patients with mild poisoning as defined by absence of loss of consciousness and maximum measured COHb level less than 15% found that even one-third of these individuals had neurocognitive sequelae up to 12 months after exposure.³⁰ This was no different than that occurring in the severely poisoned group, although the milder group had a much longer duration of exposure as well as a greater delay to COHb level drawn. Brain imaging studies have confirmed that mild exposures, marked by no LOC and COHb levels lower than 15%, may result in visible changes.^{58,143} Taken to its logical but impractical conclusion, because even apparently mild cases of CO poisoning may have poor neurocognitive outcomes, HBO treatment of every CO-exposed patient, regardless of severity, could be justified.

It is still unclear if mild neurologic symptoms, such as confusion, headache, dizziness, visual blurring, or abnormal mental status testing on initial presentation after CO poisoning, are prognostic for cognitive sequelae, which would necessitate HBO treatment. These symptoms simply represent CO poisoning, which, at COHb levels approaching 10% in volunteers, may cause temporary impairment of learning and memory.³ In one prospective clinical trial of CO poisoning, the incidence of cerebellar dysfunction portended a higher incidence of cognitive sequelae (odds ratio, 5.7 {95% confidence interval, 1.7–19.3}).¹⁹⁶ Therefore, difficulty with finger-to-nose, heel-to-shin, rapid alternating hand movements, or even ataxia, should be considered indications for HBO. Patients with other mild neurologic findings, such as

headache, warrant at least several hours of oxygen by non-rebreather facemask until symptoms resolve. If symptoms do not resolve, HBO may be considered; however, any delay in HBO may decrease its efficacy.

A more promising method to discern patients who may respond to HBO may be the genotype, apolipoprotein E, specifically the isoform $\mu 4$.⁸⁹ This particular polymorphism allele is present in up to one-quarter of the population, and it is associated with worse neurologic outcome from trauma and stroke. In the presence of CO poisoning, it is associated with lack of response to HBO for preventing neurocognitive sequelae. Further studies may support not treating patients with this particular allele, focusing on those with the potential for response to HBO therapy.

Because of the confusion in determining which CO poisoned patients really need HBO treatment, several professional societies have developed evidence-based guidelines. As alluded to previously, the American College of Emergency Physicians has noted that no clinical variable can be used to predict patients at risk of cognitive sequelae and therefore most likely to benefit from HBO.²⁰¹ Similarly, the Cochrane Collaboration review on the use of HBO in CO poisoning concluded that because of so much conflicting data, there is insufficient evidence to support HBO for CO poisoning at this time.¹⁶ The collective odds ratio for protective effect at 4 to 6 weeks with HBO versus normobaric oxygen was 0.78 [95% CI 0.54–1.12] based on a collective experience of 1361 patients in six studies. The most recent guideline from the UHMS states that CO-poisoned patients should be referred for HBO if they have serious poisoning, such as unconsciousness, whether it is transient or persistent; age 36 years or older; or CO exposure duration of 24 hours or longer, even if intermittent.¹⁹⁵ This is all consistent with the prior studies discussed earlier. The UHMS guidelines also state that many physicians treat when neuropsychologic testing is abnormal or COHb levels are greater than 25% to 30%.

Some authors recommend selective use of HBO because of cost and difficulties in transport if the primary facility lacks a chamber. However, complications that may make such transfers and treatment unsafe are rare.¹⁵⁶ At the present time, we routinely recommend HBO for selected patients poisoned by CO based on the indications in [Table 125-4](#). Fortunately, even without HBO, anywhere from one-third to three-quarters of cases with persistent cognitive sequelae resolve over the subsequent year.^{34,196}

Delayed Administration of Hyperbaric Oxygen. The optimal timing and number of HBO treatments for CO poisoning is unclear. Patients treated later than 6 hours after exposure tend to have worse outcomes in terms of delayed sequelae (30% vs. 19%) and mortality (30% vs. 14%).⁶⁹ This may explain the failure of one of the first randomized trials on HBO in CO, which had a mean time to treatment of over 6 hours after poisoning.¹⁵² Meanwhile, HBO treatments delivered within 6 hours after poisoning in patients with loss of consciousness after CO seem to almost completely prevent neurologic sequelae.²⁰⁷ However, patients may benefit if they are treated even later. In the most recent randomized clinical trial showing beneficial effects of HBO, although all patients were treated within 24 hours of exposure, 38% of patients were treated later than 6 hours after exposure. Therefore, it is not unreasonable to consider HBO, contingent on transport limitations, within 24 hours of presentation for symptomatic acute poisoning.

One case series suggests beneficial effects for HBO used up to 21 days after exposure, even after patients have developed neuropsychologic sequelae.¹²⁷ The problem with studies showing HBO benefits days after an acute poisoning or after chronic poisoning is that these cases are all anecdotal and lack control subjects. In fact, delayed neurocognitive sequelae frequently resolve within 2 months in patients with mild CO poisoning,¹⁸⁰ and in those with serious CO poisoning who survive to HBO treatment, one-third resolve within one year.¹⁹⁶ It is possible that these delayed or chronic cases may simply represent the placebo effect of HBO.

Repeat Treatment with Hyperbaric Oxygen. A randomized clinical trial demonstrated that three HBO treatments within the first 24 hours improved cognitive outcome.¹⁹⁶ Unfortunately, there was no group treated with only one or two HBO sessions in that study. Regardless, multiple treatments are advocated for patients who have persistent symptoms, particularly coma, and do not clear after their first HBO session. In a pilot study, one hyperbaric oxygen treatment was enough to promote almost total mitochondrial cytochrome activity, as measured in peripheral lymphocytes, after CO poisoning.⁵⁹ In a nonrandomized retrospective study, CO-poisoned patients who received a second HBO treatment had a reduction in delayed neurologic sequelae from 55% to 18% compared with control subjects who had only one treatment.⁶⁸

It is not clear that more HBO treatments are better. A large recent study showed that in seriously poisoned CO patients, two hyperbaric treatments resulted in a worse outcome than one treatment, with complete recovery 47% versus 68% respectively.⁴ There were serious flaws in that study, including lack of formal neuropsychological testing and the use of only 2.0 ATA of pressure, well below the 3.0 ATA used initially in favorable studies. With the lack of prospective studies comparing single versus multiple courses of HBO therapy, multiple treatments cannot be recommended routine at this time. The most recent clinical guidelines from the UHMS state that the optimal number of HBO treatments for CO poisoning is unknown and that one should consider reserving multiple treatments for patients who fail to fully recover after one treatment.¹⁹⁵

TREATMENT OF PREGNANT PATIENTS

The management of CO exposure in the pregnant patient is difficult because of the potential adverse effects of both CO and HBO. A literature review of all CO exposures during pregnancy revealed a high incidence of fetal CNS damage and stillbirth after severe maternal poisonings.¹⁸⁸ A series of three severely symptomatic patients who did not receive HBO had adverse fetal outcomes: two stillbirths and one case of cerebral palsy.⁹⁹ There have even been cases of limb malformations, cranial deformities, and a variety of mental disabilities in children poisoned in utero.^{18,110,111} A recent epidemiological study in Guatemala showed that CO exposure from wood smoke during the third trimester was inversely associated with neuropsychological performance at ages 6 to 7 years when corrected for socioeconomic confounders.⁵⁰

Traditionally, it was thought that fetal hemoglobin had a high affinity for CO. Pregnant ewe studies show a delayed but substantive increase in COHb levels in fetuses, exceeding the level and duration of those in the mothers.¹¹¹ Thus, it appeared that fetuses are a sink for CO and could be poisoned at levels lower than mothers. However, such data may not apply to humans because in vitro work shows that as opposed to sheep, human fetal hemoglobin actually has less affinity for CO than maternal hemoglobin, at a ratio of 0.8. Under conditions of low oxygenation and high 2,3-BPG, as in serious CO poisoning, the affinity of human fetal hemoglobin starts to approach that of maternal.¹⁹⁹ The more important issue with maternal CO exposure is the precipitous decrease in fetal arterial oxygen content that occurs within minutes at CO concentrations of 3000 ppm.⁶⁴ Therefore, the ensuing hypoxia of the fetus, rather than increase in fetal COHb, may be of more concern.

Maternal COHb levels do not accurately reflect fetal hemoglobin or tissue levels.⁴⁴ In primate studies, a single CO exposure insufficient to cause clinical disease in the mother led to intrauterine hypoxia, fetal brain injury, and increased rate of fetal death.^{64,65} In humans, there are a few cases of fetal demise with maternal levels of COHb less than 10%.¹⁸ However, in that series, some mothers were treated with oxygen before obtaining their COHb levels. Another issue with some of these data is that often the mother has been chronically “soaked” with CO, making levels difficult to interpret. Rodent studies show that chronic low level CO exposure in pregnant mothers may result in permanent cognitive deficits in the subsequent progeny.⁴⁸

Because maternal COHb does not necessarily predict fetal demise, clinicians must direct their attention to maternal symptoms of CO toxicity. Multiple case series demonstrate that pregnant women who present with normal mental status and no loss of consciousness after CO poisoning have excellent outcomes in terms of normal deliveries.^{18,99} These infants have no subsequent delay in attaining their developmental milestones. Therefore, it appears that mothers who appear well after acute CO poisoning will have good outcomes with respect to their pregnancies.

The bigger dilemma for clinicians is the approach to treatment of seriously symptomatic CO-poisoned pregnant patients. All patients should receive 100% oxygen by facemask, at least until the mother is asymptomatic. However, CO absorption and elimination are slower in the fetal circulation than in the maternal circulation.¹¹¹ A mathematical model predicts that elimination of CO from fetuses takes 3.5 times longer than maternal CO elimination.⁸⁶ However, based on the fact that some of these data are based on sheep fetal hemoglobin kinetics, the optimum time for treatment of the mother cannot be recommended at this time.

For exposed pregnant women with a loss of consciousness or high COHb levels, HBO might be considered. Unfortunately, pregnant patients were excluded from all prospective trials documenting efficacy of HBO. However, treatment of pregnant patients with HBO is not without theoretical risk. Animal studies show conflicting results on the effects of HBO on fetal development. Some studies have shown that HBO causes developmental abnormalities in the central nervous, cardiovascular, and pulmonary systems of rodent fetuses. This is in marked contrast to the extensive Russian experience, in which hundreds of pregnant women were treated with HBO, apparently without significant perinatal complications and with improvement in fetal and maternal status for their underlying conditions of toxemia, anemia, and diabetes.¹²¹ Cases in the United States have been published in which HBO used for mild CO poisoning resulted in infants who were normal at birth. However, less than optimal outcomes have occurred in cases of sicker patients in which the mother has had loss of consciousness or presented comatose.⁵⁴ Thus, it appears that HBO should be safe and have the same efficacy for pregnant patients as in nonpregnant patients. However, its effect in preventing adverse fetal outcomes is unclear.

There currently is no scientific validation for an absolute level at which to provide HBO therapy for a pregnant patient with CO exposure. Arbitrarily, COHb levels greater than 20% are recommended as an indication in a pregnant patient regardless of symptoms. Pregnant patients should not be treated any differently if they meet criteria for HBO that have already been mentioned (Table 125–4). Additional criteria include any signs of fetal distress, such as abnormal fetal heart rate.

TREATMENT OF CHILDREN

It has been suggested that children are more sensitive to the effects of CO because of their increased respiratory and metabolic rate.³³ Epidemiologic studies suggest that children can become symptomatic at COHb levels less than 10%,

which is lower than commonly expected in adults.⁹⁸ The other problem is that these patients may have unusual presentations. Although most children manifest nausea, headache, or lethargy, an isolated seizure or vomiting may be the only manifestation of CO toxicity in an infant or child.

While obtaining COHb levels in infants, clinicians must be aware of two confounding factors. First, many cooximeters give falsely elevated COHb levels in proportion to the amount of fetal hemoglobin present.¹⁹⁰ Second, CO is produced during breakdown of protoporphyrin to bilirubin. Therefore, infants normally have higher levels of COHb, which are even higher in the presence of kernicterus. Some neonates not exposed to CO can have COHb cooximetry readings approaching 8%.¹⁹¹ Thus, before it is assumed that an elevated COHb level implies CO poisoning in an infant, the contribution of jaundice and fetal hemoglobin must be considered in the final analysis.

Although children may be more susceptible to acute toxicity with CO, their long-term outcomes appear to be more favorable than adults. In a series of 2360 serious CO cases, all incidences of delayed neurologic sequelae were in adults older than age 30 years.³⁴ Pediatric series of CO poisoning demonstrated an incidence of delayed neurologic sequelae of 10% to 20% of children after severe CO poisoning.³³ This low incidence, in patients treated only with 100% oxygen at 1.0 ATA, has been used as an argument to avoid HBO. However, there still is a real risk of such sequelae, and HBO has been used successfully to prevent it.²⁰⁴ Children do well with HBO treatment, with mortality mainly related to concomitant smoke inhalation if present.³⁶ If the use of surface-pressure oxygen is selected to treat a child, it is comforting to know that the COHb half-life is approximately 44 minutes, faster elimination than that seen in adults.⁹⁸ Often, children exposed to CO in similar circumstances, but appear well, are treated simultaneously with the sick parent, especially if a multiplace chamber is available.

NOVEL NEUROPROTECTIVE TREATMENTS

A variety of neuroprotective agents have been tested in animal models. They are targeted primarily at preventing the delayed neurologic sequelae associated with serious CO poisoning. One of the simplest treatments tested is insulin. Hyperglycemia exacerbates neuronal injury from stroke as well as in arrest situations. In CO poisoning of rodents, it is associated with worse neurologic outcome.¹³⁸ However, insulin, independent of its glucose-lowering effect, may be the protective agent after ischemia. In rodent studies, improved neurologic outcome, as measured by locomotor activity, occurs after those with CO poisoning treated with insulin. In light of these findings, it is reasonable to aggressively treat documented hyperglycemia with insulin in patients with serious CO poisoning.

Many neuroprotective agents involve blockage of excitatory amino acids that are implicated in neuronal cell death after CO poisoning. Pretreatment of mice with dizocilpine (MK-801), which blocks the action of glutamate at N-methyl-D-aspartate receptors, ameliorates learning, memory, and hippocampal deficits with CO poisoning.⁹³ Ketamine, another glutamate antagonist, decreases the mortality rate of rats poisoned with CO after carotid ligation.¹³⁹ Treatment of mice with various glutamate antagonists prevents learning and memory deficits in a model of CO poisoning.⁶² Blockage earlier in the immunologic cascade, with a neuronal NO synthase inhibitor also prevented NMDA receptor activation, thus protecting mice from learning deficits after CO poisoning.¹⁷⁵ One exciting approach is the use of antioxidants, such as dimethyl sulfoxide and disulfiram, that prevent learning and memory deficits when given after CO poisoning in mice.⁶² Use of these or related therapeutics, although promising, awaits further animal testing because of potential adverse effects.

Other modalities have been tested in preventing neuronal damage from CO without much success. Hypothermia, rather than being beneficial, actually increases mortality in animals.¹⁶² Allopurinol which prevents formation of free radicals through xanthine oxidase inhibits lipid peroxidation in CO poisoning when given prior to exposure.¹⁶⁸ This strategy has not been promising because of the necessity for pretreatment.

PREVENTION

Early diagnosis prevents much of the morbidity and mortality associated with CO poisoning, especially in unintentional exposures. The increased quality of home CO-detecting devices allows personal intervention in the prevention of exposure.¹⁰¹ If a patient presents complaining that his or her CO alarm sounded, it is important to realize that the threshold limit for the alarm is set roughly to approximate a COHb level of 10% at worst. Therefore, manufacturers must have their alarms activate within 189 minutes at 70 ppm CO, 50 minutes at 150 ppm, and 15 minutes at 400 ppm (Underwriters Laboratories, UL2034). Alarms are not to activate for prolonged exposures below 30 ppm to prevent epidemic alarms during winter thermal inversions in large cities.⁹ Government ordinances for obligatory CO alarms could potentially prevent many poisonings, particularly during winter storms.^{22,70} Although most serious CO poisonings are associated with the absence of CO alarms, a recent series of such patients showed that even with alarms, patients become seriously poisoned.³⁸

Routine laboratory screening of ED patients during the winter is not very efficacious in diagnosing unsuspected CO

poisoning; the yield is less than 1% when patients are tested in whom the diagnosis of CO exposure was already excluded by history. Instead, selecting patients with CO-related complaints, such as headache, dizziness, or nausea, increases the yield to 5% to 11%.^{53,161} During the winter, risk factors such as gas heating or symptomatic cohabitants in patients with influenzalike symptoms such as headache, dizziness, or nausea, particularly in the absence of fever, is the most useful method for deciding when to obtain COHb levels for potential patient.

The issue of symptomatic cohabitants is especially important from a preventive standpoint. Alerting other cohabitants to this danger and effecting evacuation may prevent needless morbidity and mortality. This is especially critical for multifamily domicile, like hotels, that have resulted in dramatic collective exposures and even deaths.¹⁹⁴ Most communities have multiple resources for onsite evaluation. Usually the local fire department or utility company can either check home appliances or measure ambient CO concentrations with portable monitoring equipment. Current workplace standard for ambient CO exposures is 35 ppm averaged over 8 hours with a ceiling limit of 200 ppm (measured over a 15-minute period).¹²⁹ Just a 4-hour exposure to 100 ppm of CO may result in COHb level greater than 10% with symptoms.

SUMMARY

- Unintentional exposures to CO are easily missed or misdiagnosed. Patients with a suspected influenzalike illness should be screened for potential home sources of CO, and symptomatic cohabitants should be alerted.
- CO exposure should also be considered in patients with unexplained coma, acidosis, or signs of cardiac ischemia, especially if attempted suicide is suspected.
- Fire victims, in addition to airway complications and potential cyanide toxicity, may succumb to CO toxicity.
- The mainstay of treatment in CO poisoning is good supportive care with early oxygenation to increase the elimination of COHb.
- Because of the overwhelming clinical successes with HBO and its limited risks, early use of this treatment modality in severe exposures is encouraged.
- Discussion with a regional poison center or hyperbaric facility will help in identifying patients who are most likely to benefit from such treatment.

A38 ANTIDOTES IN DEPTH

Hyperbaric Oxygen

Stephen R. Thom

INTRODUCTION

Hyperbaric oxygen (HBO) is used therapeutically in poisoning by carbon monoxide (alone or if complicated by cyanide poisoning), methylene chloride, hydrogen sulfide, and carbon tetrachloride. It is also a recognized therapy for air or gas embolism, such as may arise from ingestion of hydrogen peroxide, and for anemia, a functional form of which arises from oxidants that induce methemoglobinemia.

HISTORY

Hyperbaric medicine became established as a clinical discipline in the later half of the 20th century with a focus on treatment of decompression sickness. Utilization of hyperbaric chambers has expanded in the past 60 years with improved understanding of basic mechanisms of action. The first case reports of HBO for documented CO poisoning appeared in 1960,¹⁹² and the consistent application of HBO in CO poisoning began in many centers at that time.¹⁹⁰ The first report presenting statistical evidence of the superiority of HBO compared to normobaric oxygen in CO poisoning, as well as a description of the “late syndrome,” was published in 1969.⁷⁴

PHARMACOLOGY

Chemistry and Preparation

In hyperbaric oxygen (HBO) therapy the patient breathes 100% O₂ while exposed to increased atmospheric pressure. Treatments are performed in either a monoplace (single patient) or a multiplace (typically 2–14 patients) chamber. Pressures applied while patients are in the chamber usually are 2 to 3 atmospheres absolute (ATA), where sea level air pressure equals 1 ATA. Treatments generally last for 1.5 to 8 hours, depending on the indication, and may be performed one to three times daily. Monoplace chambers usually are compressed with pure oxygen. Multiplace chambers are pressurized with air, and patients breathe pure oxygen through a tight fitting face mask, a head tent, or endotracheal tube as clinically indicated.

Mechanisms of Action

Therapeutic mechanisms of action for HBO are based on elevation of both hydrostatic pressure and the partial pressure of oxygen. Elevation of the hydrostatic pressure reduces the volume of a gas according to Boyle’s law (within a closed system, absolute pressure and volume of a given mass of a confined gas are inversely proportional, if the temperature remains unchanged). This action has direct relevance to pathologic conditions in which gas bubbles are present in the body, such as arterial gas embolism, decompression sickness, and ingestion of concentrated solutions of hydrogen peroxide (H₂O₂). During treatment, the arterial oxygen tension typically exceeds 1500 mm Hg and achieves tissue oxygen tensions of 200 to 400 mm Hg—over fivefold higher than when breathing air.²⁰³ While one is breathing air under normal environmental conditions, hemoglobin is saturated with oxygen on passage through the pulmonary microvasculature, and the primary effect of HBO is to increase the dissolved oxygen content of plasma. In addition, HBO affects neutrophil adhesion to blood vessels and restores mitochondrial, neutrophil, and immunologic disturbances caused by CO poisoning.

Pharmacokinetics

Oxygen inhaled at hyperbaric pressure is rapidly absorbed. Application of each additional atmosphere of pressure while breathing 100% oxygen increases the dissolved oxygen concentration in the plasma by 2.2 mL O₂/dL (vol%) (Chap. 29). In five human subjects performing breath holds during compression to 20 m, oxygen consumption also significantly increased,

which was attributed to increased cardiac output.¹²⁵ Animal models of focal ischemia suggest that hyperbaric oxygen rapidly distributes to target organs to improve penumbral oxygenation.¹⁹⁹ HBO increases tissue oxygen concentration and wound oxygen delivery in humans.¹⁷² Regarding pharmaceutical interactions, hyperbaric hyperoxia does not appear to produce appreciable alterations in the pharmacokinetics of pentobarbital, salicylate, or theophylline in canine models^{111–113} or gentamicin in healthy human volunteers.¹⁴²

Pharmacodynamics

There are transient benefits from HBO for reducing bubble volume in disorders such as air embolism and also oxygenating tissues in conditions where hemoglobin-based O₂ delivery is impaired. These rather straightforward mechanisms form the basis for using HBO for patients with massive ingestions of hydrogen peroxide (H₂O₂) associated with intravascular gas embolism and for life-threatening poisonings from cyanide (CN), hydrogen sulfide (H₂S), and exposure to oxidizers causing methemoglobin. HBO is also used for carbon tetrachloride (CCl₄) poisoning, where acute application of oxygen and pressure may inhibit the cytochrome P450 oxidase system responsible for producing hepatotoxic free radicals.^{30,136} HBO also has well described vasoconstriction effects,^{38,197,216} compared to dynamic CO-associated effects on cerebral vasodilation.¹²²

Recent years have shown that benefits persisting beyond the short period when a patient is in a hyperbaric chamber are related to production of reactive oxygen species (ROS) and reactive nitrogen species (RNS).^{206,207} Reactive species can have positive and negative effects that depend on the concentration of reactant generated and its intracellular localization. Hence, with regard to HBO as with any drug, the precise dose may define the risks and benefits of therapy. Because exposure to hyperoxia in typical clinical HBO protocols is rather brief, most studies show that antioxidant defenses are adequate to avoid tissue injuries.^{52,53,173,220}

There are at least three separate therapeutic mechanisms supporting the use of O₂ when treating carbon monoxide (CO) poisoning. Administration of supplemental O₂ is a historical cornerstone for treatment based on reducing body burden of carboxyhemoglobin (COHb). Elevated COHb can result in tissue hypoxia, and exogenous O₂ both hastens dissociation of CO from hemoglobin and provides enhanced tissue oxygenation directly through the increased PO₂. HBO causes COHb dissociation to occur at a rate greater than that achievable by breathing 100% O₂ at sea level pressure.¹⁵⁸ Additionally, HBO accelerates restoration of mitochondrial oxidative processes.²⁸ Among the earliest events observed in both an animal model and in humans suffering CO poisoning is platelet-neutrophil interactions that mediate intravascular neutrophil activation. These changes precipitate neutrophil adherence to blood vessel walls that initiate vascular changes and a cascade of events leading to neurological dysfunction (Fig. A38–1).^{96,208,213} Immunological responses to altered myelin basic protein (MBP) cause neurological dysfunction in animals, and presence of MBP in cerebrospinal fluid of CO poisoned patients is suggested as a predictive marker for onset and persistence of CO-mediated encephalopathy.^{17–19,94,95,102}

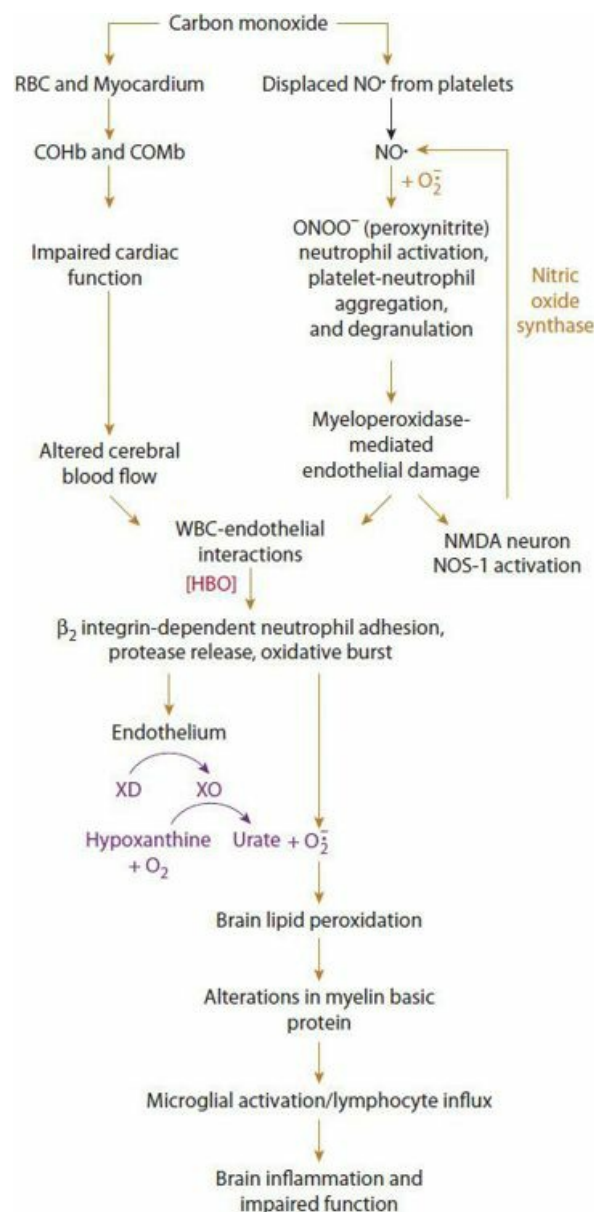

FIGURE A38–1. The final common pathway demonstrating concurrent events leading to vascular injury with CO poisoning and the sequence of events leading to neurological injuries. • = peroxynitrite, NO • = nitric oxide, O₂ • = superoxide radical, COHb = carboxyhemoglobin, COMb = carboxymyoglobin, NMDA = N-methyl-D-aspartate neurons, NOS-1 = neuronal nitric oxide synthase, NO₂ = nitrite (major oxidation product of NO•), WBC = leukocytes, XD = xanthine dehydrogenase, XO = xanthine oxidase.

Animals poisoned with CO then treated with HBO have more rapid improvement in cardiovascular status,⁵⁸ lower mortality,¹⁶¹ and lower incidence of neurological sequelae.^{84,205} Benefits are likely based on improved oxygenation and mitochondrial function as well as inhibition of neutrophil adhesion. Exposure to 2.8 to 3.0 ATA O₂ for 45 minutes temporarily inhibits neutrophil adherence to endothelium mediated by the activation-dependent β₂-integrins on the neutrophil membrane in both rodents and humans.^{41,101,114,204,214} The ability of HBO to inhibit function of neutrophil β₂-integrin adhesion molecules in animal models forms the basis for amelioration of encephalopathy resulting from CO poisoning and decompression sickness, smoke-induced lung injury, as well as reperfusion injuries of brain, heart, lung, liver, and skeletal muscle.^{8,105,135,200,201,204,217,221,226,240–242} HBO inhibits neutrophil β₂ integrin expression but not its expression on other circulating leukocytes due to RNS generation by type-2 nitric oxide synthase and myeloperoxidase present in neutrophil-specific α-granules. That is, it is the presence of both enzymes within the same granules that is required to generate the requisite RNS to impair neutrophil adherence. The reaction leads to excessive S-nitrosylation of cytoskeletal β actin, which in turn impedes the function of β₂ integrins.²¹⁰ This leads to modifications in cytoskeletal regulation of a number of proteins.^{211,212} It is important to comment that HBO does not reduce neutrophil viability, and functions such as degranulation and oxidative burst in response to chemoattractants remain intact.^{204,211,214} This contrasts with alternative interventions such as monoclonal antibodies which can inhibit β₂ integrins and ameliorate ischemia-reperfusion injuries but cause profound immunocompromise.^{144,145}

ROLE IN CARBON MONOXIDE POISONING

Survivors of CO poisoning are faced with potential impairments to cardiac and neurological functions. CO poisoning can cause acute cardiac compromise, and survivors exhibit an increased risk for cardiovascular related death in the subsequent 10 years.^{88,175} Some patients exhibit acute abnormalities wherein they have impaired consciousness and or focal neurological findings from the time of initial presentation and never recover.^{3,47,50,69} Other patients seemingly recover from acute poisoning but then manifest neurological or neuropsychiatric abnormalities from 2 days to about 5 weeks after poisoning.^{42,55,73,92,131,139,143,152,166,183,186,215,235} Events occurring after a clear or “lucid” interval are termed “subacute or delayed” neurological sequelae. These terms have gained popularity and may have some clinical utility, but animal studies suggest neuropathology is more of a continuum. That is, various pathways of injury occur in close proximity, and in some cases they occur concomitantly.^{68,97,140,153,208,209,213}

Since 1960, HBO has been used with increasing frequency for severe CO poisoning because clinical recovery appeared to improve beyond that expected with ambient pressure oxygen therapy. Support for HBO use comes from this experience.^{73,74,93,115,138,152,155,171} The clinical efficacy of HBO for acute CO poisoning has been assessed in six prospective, randomized trials published in peer-reviewed journals. Only one clinical trial satisfies all items deemed to be necessary for the highest quality of randomized controlled trials.²³⁵ This double-blinded, placebo-controlled clinical trial involved 152 patients, who received treatment with either three sessions of HBO therapy or normobaric O₂ with sham pressurization to maintain blinding. The group treated with HBO had a lower incidence of cognitive sequelae than the group treated with NBO after adjustment for pre-treatment cerebellar dysfunction and stratification (odds ratio 0.45, 95% confidence interval 0.22–0.92, $p = 0.03$).

The only other blinded, prospective, randomized trial was published in 1999, and it involved 191 patients of different severity treated with either daily HBO (2.8 ATA for 60 minutes) with intervening high flow oxygen for 3 or 6 days versus high flow normobaric oxygen for 3 or 6 days.¹⁷⁸ Additional HBO treatments (up to six daily) were performed in patients without adequate neurological recovery. The primary outcome measure for this trial was testing performed at completion of treatment (3–6 days) and not from long term follow-up. This study had a high rate of adverse neurological outcomes in all patients, regardless of treatment assignment. Neurological sequelae were reported in 74% of HBO treated patients and in 68% of controls. No other clinical trial has described this magnitude of neurological dysfunction. The high incidence may be related to the assessment tool which could not discern true neurological impairments from poor test taking related to depression.¹⁷⁹ Suicide attempts with CO represented 69% of cases in this trial. Moreover, 54% of subjects were lost to follow-up. Outcomes at one month were not reported, but were stated to show no difference. Multiple statistical comparisons were reported without apparent planning or the requisite statistical correction. Both treatment arms received continuous supplemental mask O₂ for 3 days between their hyperbaric treatments (both true HBO and “sham”), resulting in greater overall O₂ doses than conventional therapy. Multiple flaws in the design and execution of this study are discussed in the literature, so it is impossible to draw meaningful conclusions from the data.^{80,148} Despite these issues, conclusions from this trial have been accepted in systematic reviews.^{29,238}

Other randomized trials of HBO for CO poisoning were not blinded. The first prospective clinical trial involving HBO therapy did not demonstrate therapeutic benefits.¹⁶⁶ This study was criticized because the authors used a low oxygen partial pressure (2 ATA) versus the more usual protocols with 2.5 to 3 ATA, an unvalidated questionnaire to assess neurological function, and because nearly half of the patients received hyperbaric treatments more than 6 hours after they were identified.²⁷ This 1989 study protocol was used again in a more recent trial with no modifications despite the criticisms voiced over a decade earlier. Not surprisingly, the outcome was virtually the same. If study results are expressed on an intention-to-treat basis, patients with transient loss of consciousness had an incidence of neurological sequelae based on the self-assessment questionnaire of 48%, and those treated with HBO had an incidence of 51%. Patients with initial coma who were treated once with HBO had an incidence of sequelae of 47%; patients who were treated with two HBO treatments had an incidence of sequelae of 60% (not significantly different from any of the other groups).⁶

HBO was found effective in several other prospective investigations. In a trial involving mildly to moderately poisoned patients, 23% of patients (7/30) treated with ambient pressure oxygen developed neurologic sequelae, whereas no patients (0/30; $p < 0.05$) who were treated with HBO (2.8 ATA) developed sequelae.²¹⁵ In another prospective, randomized trial, 26 patients were hospitalized within 2 hours of discovery and were equally divided between two treatment groups: ambient pressure oxygen or 2.5 ATA O₂.⁵⁵ Three weeks later, patients treated with HBO had significantly fewer abnormalities on electroencephalogram, and single-photon emission computed tomography (SPECT) scans showed that cerebral vessels had nearly normal reactivity to carbon dioxide, in contrast to diminished reactivity in patients treated with ambient pressure oxygen.

In conclusion, efficacy of HBO for acute CO poisoning is supported in animal trials, and studies provide a mechanistic basis for treatment. In this era of evidence-based medicine a great deal of emphasis has been placed on systematic reviews, which have stressed the need for new studies because of the range in quality of published clinical trials.^{29,238} Practice recommendations are published based on existing studies with the best design that most closely address the actual practical

handling of patients.⁸³ HBO should at least be considered in all cases of serious acute CO poisoning and normobaric 100% oxygen continued until the time of HBO administration. CO poisoned patients who receive three HBO treatments within 24 hours following presentation manifest approximately one half the rate of cognitive sequelae at 6 weeks, 6 months, and 12 months following treatment as those treated with only normobaric oxygen. Risk factors for long term cognitive impairment in patients not treated with hyperbaric oxygen include age >36 years, exposure >24 hours, loss of consciousness, and COHb >25%. Recommendations for children can pose special challenges, but in clinical series there appear to be no marked differences in clinical manifestations compared to those reported in adults.^{62,82,108,162} Pregnancy poses another special situation in that CO readily crosses the placenta and may cause fetal distress and fetal death. HBO has been administered safely to pregnant women, but there are no prospective studies of efficacy, so standard adult guidelines for treatment are often utilized.

Another study has shown that HBO is only beneficial in reducing neurological sequelae among patients who do not possess the apolipoprotein ε4 allele.⁸⁹ Because genotype is typically unknown, this report does not alter existing treatment guidelines, but it may become important for future research. Although the basic mechanisms are unknown, it is well established that the apolipoprotein genotype can have profound effects on risk for a variety of neuropathological events.^{1,64,141,176} Whether apolipoprotein ε4 modifies the primary pathophysiological insults of CO or the mechanisms of HBO are currently unknown. As of yet, no objective method is available for staging the severity of CO poisoning, although preliminary reports suggest plasma markers may be used in the future.²⁰⁹ Psychometric screening tests have not proved reliable because abnormalities during the initial screening do not correlate with development of delayed sequelae.²¹⁵

ROLE IN METHYLENE CHLORIDE POISONING

Methylene chloride (CH_2Cl_2) is an organic solvent used commercially in aerosol sprays, as a solvent in plastics manufacturing, in photographic film production, in food processing as a degreaser, and as a paint stripper (eg, for bathtub refinishing).³⁹ It is readily absorbed through the skin or by inhalation. Immediate effects of methylene chloride are attributable to the direct depressant actions of this solvent on the CNS and resulting hypoxia. There are two metabolic pathways involved in its metabolism: an oxidative one mediated by cytochrome P450s, mainly CYP2E1 that may involve a metabolic-switch or two-active site process, and another pathway mediated by glutathione (GSH) that involves mainly glutathione S-transferases (GST).^{59,195} The P450 pathways generate formyl chloride and CO, with a secondary conjugation of formyl chloride to GSH. The separate GSH/GST pathway involves conjugation of methylene chloride, primarily by metabolism through GST-theta, to generate CO_2 as well as DNA adducts. These GSH/GST conjugation pathway DNA adducts play a role in late-onset carcinogenesis.^{228,229} Acute methylene chloride toxicity can have many of the same manifestations as CO poisoning.¹⁹¹ Production of CO is slow, and peak COHb levels of 10% to 50% may not be reached for 8 hours or more.^{37,40,60,103,116,131,132,185,195} Effects that are present after one hour or more, particularly if the COHb level is elevated, may be partially caused by CO toxicity. Anecdotal reports of HBO treatment for methylene chloride poisoning report both success and failure, which may reflect an additional component due to solvent toxicity.^{35,109,170,174} HBO treatment recommendations, using a standard three treatment protocol, follow those in patients meeting the aforementioned considerations in CO poisoning. Additional treatments in the setting of ongoing CO production or persistent symptoms may be required.¹¹⁷ Prolonged normobaric 100% oxygen therapy may be used in patients with HBO contraindications.^{90,167}

ROLE IN COMBINED CARBON MONOXIDE AND CYANIDE POISONING

CO and CN poisonings can occur concomitantly from smoke inhalation.^{4,5,12-15,21,44,49,128,130,146,184,188,231,236} Experimental evidence suggests that they can produce synergistic toxicity.^{10,149,156,158} Animal studies demonstrate that ambient pressure 100% O_2 can protect against CN toxicity¹⁸¹ and also can enhance CN metabolism to thiocyanate when thiosulfate is used concomitantly.²³ HBO may have either direct effects on reducing CN toxicity^{48,98,99,120,202} or augment other antidotes.^{33,121,181,233} However, animal studies have not uniformly found that HBO improved outcome,²³² and clinical experience regarding CN treatment with HBO is sparse.^{3,72,180} A series of symptomatic smoke inhalation victims with elevated concentrations of both CO and CN who received HBO and treatment for CN involving sodium nitrite and sodium thiosulfate, four of five patients survived without apparent neurologic damage.⁸⁶ Clinical case reports where HBO was used along with standard antidote treatment (sodium nitrite plus sodium thiosulfate) for isolated CN poisonings are equivocal regarding benefit.^{72,126,180,218} One case showed dramatic improvement,²¹⁸ but another showed none.¹²⁶ Methemoglobin formation with the standard antidote treatment involving nitrite is not thought to generate concerning high methemoglobin concentrations, but in the setting of concomitant COHb the additional reduction of oxygen carrying capacity may pose.^{107,78} Hence, there is a special advantage for hydroxycobalamin use in combined poisonings. Further research in this area is necessary. Because CN is among the most lethal poisons and toxicity is rapid, standard antidotal therapy for isolated CN poisoning is of primary importance. Hyperbaric oxygen should be considered in any case of dual (CO and CN)

poisoning and in CN poisoning when vital signs and mental status do not improve with antidote treatment. Possible use of HBO therapy may change as data on alternative antidotes such as hydroxycobalamin are investigated. Some evidence suggests each offers supportive effects on brain metabolism.^{120,121}

ROLE IN HYDROGEN SULFIDE POISONING

Hydrogen sulfide (H_2S) binds to cytochrome a-a_3 . This is similar to CN, although it is more readily dissociated by O_2 .¹⁹⁶ Clinical manifestations of toxicity are also similar to those with CO and CN.¹⁹⁶ Management of patients with serious H_2S poisoning principally involves oxygenation and cardiovascular support, as well as consideration of antidotal therapy with sodium nitrite to induce methemoglobinemia.^{66,76,79,154} HBO may be more effective than sodium nitrite in preventing mortality in animals.²² Several clinical reports indicate that HBO, sometimes in conjunction with supplemental oxygen and blood pressure support, appears to be beneficial.^{7,16,32,77,123,191,237} Relatively late treatment with HBO (eg, over 10 hours after poisoning) is reported to be beneficial in some²²⁵ but not all cases.^{2,193} No definitive data regarding use of HBO for H_2S poisoning are available, but HBO should be considered in cases where altered mental status or unstable vital signs persist after standard resuscitation measures.

ROLE IN OXIDANT-INDUCED METHEMOGLOBINEMIA

Oxidation of ferrous (2^+) heme to the ferric (3^+) form renders hemoglobin nonfunctional, and the presence of oxidized hemoglobin varieties causes a left shift of the oxyhemoglobin dissociation curve.¹⁹⁸ Hence, the manifestations of toxicity from acquired methemoglobinemia are usually more severe than those produced by a corresponding degree of anemia. In healthy people, when the fraction of methemoglobin is 10% to 20% (~ 1.5 g/dL) patients may appear cyanotic, but otherwise asymptomatic. With approximately 30% methemoglobin, there may be vague, nonspecific symptoms such as headache, fatigue, dyspnea, tachycardia, and dizziness. Unconsciousness is common at levels above 50% and death at 70%. There are numerous anecdotal accounts of clinical improvement with HBO in patients suffering from life-threatening methemoglobinemia.^{54,70,71,75,100,119,124,177,230} Ongoing exposure to any oxidants and the potential need for methylene blue to treat methemoglobinemia (Antidotes in Depth: A42) should also be addressed.

ROLE IN CARBON TETRACHLORIDE POISONING

Carbon tetrachloride (CCl_4) induced hepatotoxicity may be diminished by HBO. Mortality was decreased in a number of animal studies,^{20,31,147,168} and there are several case reports of patients surviving potentially lethal ingestions with HBO therapy.^{118,194,219,243} Because there are no proven antidotes for CCl_4 poisoning, HBO should be used for patients with large CCl_4 exposures. However, there may be a delicate balance between oxidative processes that are therapeutic and those that mediate hepatotoxicity.²⁴ Therefore, when HBO is being considered, it should be instituted before the onset of liver function abnormalities. More recently, N-Acetylcysteine (NAC) is effective in limiting liver damage in animals and appears of clinical benefit in humans with massive ingestions.^{133,137,222,239} Additive benefit from concomitant use of NAC and HBO was shown in an animal model demonstrating a diminution of toxicity in L-arginine induced pancreatitis, but there is no experience with CCl_4 poisoning.¹⁵⁷

ROLE IN HYDROGEN PEROXIDE INGESTION

Ingestion of concentrated hydrogen peroxide (H_2O_2) solutions (eg, 35%) can result in venous and arterial gas embolism due to liberation of large volumes of O_2 . Exposure to household concentrations of H_2O_2 (3%) has resulted in symptomatic portal venous air embolism on rare occasion.¹³⁴ At standard temperature and pressure, ingestion of 1 mL of household 3% H_2O_2 liberates approximately 10 mL oxygen gas; by comparison, each milliliter of 35% hydrogen peroxide yields 115 mL of oxygen gas.¹⁵⁰ Symptoms vary with the affected organ. Seizures, alterations in mental status, and strokelike manifestations occur with CNS involvement from arterial emboli and nausea, vomiting, hematemesis, and abdominal pain with gastrointestinal and hepatic venous involvement, acute obstruction of the portal vein, portal venous hypertension, and bowel edema.^{43,91,127,160,182} HBO has been a successful intervention for portal venous gas and in some cases of impaired consciousness and or focal neurological findings.^{9,63,134,150,160,169,224} HBO reduces the volume of offending gas and improves solubility of gas into tissues and plasma.¹⁶⁰ A history of inadvertent ingestion of concentrated H_2O_2 , significant signs or symptoms, or radiologic evidence of gas embolism should prompt patient placement in a Trendelenburg, left lateral decubitus position, administration of 100% oxygen and sufficient fluids to sustain perfusion, and consideration for

immediate transportation to the nearest hyperbaric facility. HBO to treat gas embolism has demonstrated benefit even if delayed beyond 20 hours.⁵⁶

ADVERSE EFFECTS AND SAFETY ISSUES

Many HBO facilities have equipment and treatment protocols and abilities analogous to those found in an intensive care unit.^{104,227,234} The possible capabilities will vary and interventions with HBO should never be undertaken if standard patient support cannot also be achieved. The inherent toxicity of O₂ and potential for injury resulting from elevations of ambient pressure must be addressed whenever HBO is used therapeutically. Preexisting conditions that require evaluation for possible management before initiation of HBO include claustrophobia, sinus congestion, and patients with scarred or noncompliant structures in the middle ear, such as otosclerosis.¹⁰⁶ Middle ear barotrauma is the most common adverse effect of HBO treatment,³⁷ and it occurs in 1.2% to 7% of patients.^{46,164,220} When autoinsufflation fails, puncturing the ear drum or tympanostomy tube placement will resolve the problem. Pneumothorax is a rarely reported complication.²⁵ Toxicity resulting from O₂ can be manifested by injuries to the CNS, lungs, and eyes. CNS O₂ toxicity manifests as a generalized seizure and occurs at an incidence of approximately 1-4/10,000 patient treatments.^{51,85,164} Pulmonary oxygen toxicity typically does not arise when standard treatment protocols are followed.^{45,61,87,165} Progressive myopia may occur in patients undergoing prolonged daily therapy, but typically reverses within 6 weeks after treatments are terminated.¹²⁹ Nuclear cataracts can form with excessive treatments, exceeding a total of 150 to 200 hours, and they may rarely develop with standard treatment protocols.^{67,159} Absent on-site hyperbaric capability, the risks of interfacility transportation (clinical decompensation, vehicle crashes, etc) also will factor into decision making.

PREGNANCY AND LACTATION

HBO in pregnant patients presents the additional risks of fetal CNS, ocular, pulmonary, and cardiac toxicity.¹¹ In CO poisoning, these must be weighed against the potentially devastating fetal outcomes such as spontaneous abortion, intrauterine fetal demise, anatomic malformations, CNS injury, respiratory distress, and neonatal jaundice, which may occur even in only mildly symptomatic CO poisoned mothers.^{36,110} For these reasons, carboxyhemoglobin thresholds (eg, 15%–20%) for HBO therapy are often set lower for the pregnant patients than for other adults in HBO treatment algorithms. Normal fetal outcomes have followed HBO, even in the setting of severe maternal toxicity, whereas significant adverse fetal outcomes have followed normobaric oxygen therapy.¹¹⁰ A summary of over 700 Russian patients treated with HBO for various hypoxemic states did not find any detrimental HBO effects.²²³ HBO was used safely in a prospective study of 44 pregnant women poisoned by CO.⁵⁷ Multiple other case reports document successful maternal and fetal outcomes in CO poisoned pregnant patients.^{26,65,187} HBO has also been employed successfully in patients with obstetrical procedures complicated by gas embolism.¹⁵¹ Treatment decisions will ultimately be made on an individual case basis after weighing potential risks and benefits. There are no data regarding HBO effects on lactation.

DOSING AND ADMINISTRATION

Rodent and human studies demonstrate that exposure to 2.8 to 3.0 ATA O₂ for 45 minutes is required to temporarily inhibit neutrophil adherence to endothelium mediated by the activation-dependent β_2 -integrins on the neutrophil membrane.^{41,101,114,204,214} Clinical trials employing HBO at only 2 ATAs have been unable to demonstrate a benefit of HBO.^{6,166} Multiple trials using HBO (2.5 ATA or above) have demonstrated efficacy.^{55,139,215,235} One trial using HBO (2.8 ATA) was unable to demonstrate benefit, subject to the previously discussed limitations.¹⁷⁸ If undertaken, HBO therapy (2.5–3.0 ATA, weighted toward the latter) should be provided as early as possible, as a mortality benefit is demonstrated if HBO is administered within 6 hours.⁷⁴ Clinical trials have initiated therapy within 24 hours of the end of carbon monoxide exposure.²³⁵ The use of more than one treatment is supported by retrospective and prospective analysis,^{73,235} although clinical practice is highly variable in this regard.^{34,81}

FORMULATION AND ACQUISITION

HBO therapy is provided in monoplace or multiplace chambers, which are considered class II medical devices. For sites not possessing HBO capacity, various online organizational and professional directories may assist in locating hyperbaric facilities in the absence of preexisting HBO transfer protocols.

SUMMARY

- Mechanisms of action and efficacy of HBO are complex and remain an area of active investigation. Research findings are provocative because they highlight the fact that traditional assessments of mechanisms for toxicity of some xenobiotics are incomplete.
- While the efficacy of HBO for acute CO poisoning is supported in animal trials, questions persist on many issues, including patient selection, optimal dose, and session frequency.
- HBO merits consideration in serious acute CO poisoning, particularly in those cases with end organ manifestations, recognizing highly varied clinical practice scenarios and preferences.
- Further investigation is required to discern those cases where clear benefit arises with HBO treatment and to define the constraints that may limit its efficacious use.
- Anecdotal evidence supports HBO therapy in hydrogen sulfide and carbon tetrachloride poisoning, in oxidant induced methemoglobinemia, and in hydrogen peroxide ingestion.

126 CYANIDE AND HYDROGEN SULFIDE

Christopher P. Holstege and Mark A. Kirk

Cyanide	
MW	= 26.02 Da
Whole blood	< 1 µg/mL
	< 38.5 µmol/L
Concentrations	
Airborne	
Immediately fatal	= 270 ppm
Life threatening	= 110 ppm >30 minutes
Hydrogen Sulfide	
MW	= 34.08 Da
Airborne	
Odor threshold	= 0.01–0.3 ppm
Olfactory paralysis	= 100–150 ppm
Immediately fatal	= 1000 ppm

CYANIDE POISONING

History and Epidemiology

Cyanide exposure is associated with smoke inhalation, laboratory mishaps, industrial incidents, suicide attempts, and criminal activity.^{39,113} Cyanide is a chemical group that consists of one atom of carbon bound to one atom of nitrogen by three molecular bonds ($C\equiv N$). Inorganic cyanides (also known as cyanide salts) contain cyanide in the anion form (CN^-) and are used in numerous industries, such as metallurgy, photographic developing, plastic manufacturing, fumigation, and mining. Common cyanide salts include sodium cyanide ($NaCN$) and potassium cyanide (KCN). Sodium salts react readily with water to form hydrogen cyanide. Organic compounds that have a cyano group bonded to an alkyl residue are called nitriles. For example, methyl cyanide is also known as acetonitrile (CH_3CN). Hydrogen cyanide (HCN) is a colorless gas at standard temperature and pressure with a reported bitter odor. Cyanogen gas, a dimer of cyanide, reacts with water and breaks down into the cyanide anion. Cyanogen chloride ($CNCl$) is a colorless gas that is easily condensed; it is a listed agent by the Chemical Weapons Convention.

Many plants, such as the *Manihot* spp, *Linum* spp, *Lotus* spp, *Prunus* spp, *Sorghum* spp, and *Phaseolus* spp contain cyanogenic glycosides.¹¹¹ The *Prunus* species consisting of apricots, bitter almond, cherry, and peaches have pitted fruits containing the glucoside amygdalin. When ingested, amygdalin is biotransformed by intestinal β -d-glucosidase to glucose, aldehyde, and cyanide (Fig. 126–1). Laetrile, which contains amygdalin, was inappropriately suggested to have antineoplastic properties despite a lack of evidence to support such claims.⁸³ When laetrile was administered by intravenous infusion, amygdalin bypassed the necessary enzymes in the gastrointestinal tract to liberate cyanide and did not cause toxicity. However, ingested laetrile can cause cyanide poisoning. Despite data demonstrating its lack of utility in the treatment of cancer, it still is available via the Internet.

FIGURE 126–1. Biotransformation of cyanogens (**A**) acetonitrile and (**B**) amygdalin to cyanide.

Cassava (*Manihot esculenta*) root is a major source of food for millions of people in the tropics. It is a hardy plant that can remain in the ground for up to 2 years and needs relatively little water to survive. Because the shelf life of a cassava root is short once it is removed from the stem, cassava root must be processed and sent to market as soon as it is harvested. However, proper processing must occur to assure the food's safety. Processed cassava is called Gari. Linamarin (2-hydroxy-4-oxo-4-phenylbutanenitrile-β-D-glycoside) is the major cyanogenic glycoside in cassava roots. It is hydrolyzed to hydrogen cyanide and acetone in two steps during the processing of cassava roots.¹²⁴ Soaking peeled cassava in water for a single day releases approximately 45% of the cyanogens, whereas soaking for 5 days causes 90% loss. If processing is inefficient, linamarin and cyanohydrin, the immediate product of hydrolysis of linamarin, remain in the food.⁹² Consumed linamarin is hydrolyzed to cyanohydrin by β-glucosidases of the microorganisms in the intestines. Cyanohydrin present in the food and formed from linamarin then dissociates spontaneously to cyanide in the alkaline pH of the small intestines.

Iatrogenic cyanide poisoning may occur during use of nitroprusside for the management of hypertension. Each nitroprusside molecule contains five cyanide molecules, which are slowly released in vivo. If endogenous sulfate stores are depleted, as in the malnourished or postoperative patient, cyanide may accumulate even with therapeutic nitroprusside infusion rates (2–10 μg/kg/min).

In 1782, the Swedish chemist Carl Wilhelm Scheele first isolated hydrogen cyanide. He reportedly died from the adverse health effects of cyanide poisoning in 1786. Napoleon III was the first to employ hydrogen cyanide in chemical warfare, and it was subsequently used on World War I battlefields. During World War II, hydrocyanic acid pellets (brand name Zyklon B) caused more than one million deaths in Nazi gas chambers at Auschwitz, Buchenwald, and Majdanek. In 1978, KCN was used in a mass suicide led by Jim Jones of the People's Temple in Guyana, resulting in 913 deaths. Other notorious suicide cases include Wallace Carothers, Herman Goring, Heinrich Himmler, and Ramon Sampedro. In 1982,

seven deaths resulted from consumption of cyanide-tainted acetaminophen in Chicago that subsequently lead to the requirement of tamper-resistant pharmaceutical packaging. Numerous copycat murders subsequently have occurred using cyanide-tainted capsules, with the last high-profile case occurring in 2010 involving an Ohio emergency medicine physician who murdered his wife with a cyanide-laden calcium capsule.¹⁴ Cyanide has also been used for illicit euthanasia.²⁰

Cyanide poisoning accounted for 1148 exposures reported to the American Association of Poison Control Centers from 2007 to 2011 (Chap. 136).²⁴ One study of poison center data found that 8.3% of intentional overdose cases died and another 9% developed cardiac arrest but survived; 74% did not receive an antidote, most likely due to the failure of the initial treatment team to recognize the poisoning.¹³ The majority of reported cyanide exposures are unintentional. These events frequently involve chemists or technicians working in laboratories where cyanide salts are common reagents.¹⁹ The potential for cyanide poisoning also exists following smoke inhalation, especially following the combustion of materials such as wool, silk, synthetic rubber, and polyurethane.^{8,30,108} Ingestion of cyanogenic chemicals (ie, acetonitrile, acrylonitrile, and propionitrile) is another source of cyanide poisoning.¹¹⁵ Acetonitrile (C_2H_3N) and acrylonitrile (C_3H_3N) are themselves nontoxic, but biotransformation via cytochrome P450 liberates cyanide (Fig. 126–1).¹²⁶

Pharmacology

The dose of cyanide required to produce toxicity is dependent on the form of cyanide, the duration of exposure, and the route of exposure. However, cyanide is an extremely potent toxin with even small exposures leading to life-threatening symptoms. For example, an adult oral lethal dose of KCN is approximately 200 mg. An airborne concentration of 270 ppm ($\mu\text{g/mL}$) of hydrogen cyanide (HCN) may be immediately fatal, and exposures >110 ppm for more than 30 minutes are generally considered life threatening. The current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for both hydrogen cyanide and cyanogen is 10 ppm as an 8-hour time-weighted average (TWA) concentration. The Immediately Dangerous to Life or Health (IDLH) value for hydrogen cyanide is 50 ppm.

Acute toxicity occurs through a variety of routes, including inhalation, ingestion, dermal, and parenteral. Hydrogen cyanide readily crosses membranes because it has a low molecular weight (27 Da) and is nonionized. After absorption and dissolution in blood, cyanide exists in equilibrium as the cyanide anion (CN^-) and undissociated HCN. Hydrogen cyanide is a weak acid with a pK_a of 9.21. Therefore, at physiologic pH 7.4 it exists primarily as HCN. Rapid diffusion across alveolar membranes followed by direct distribution to target organs accounts for the rapid lethality associated with HCN inhalation.

Toxicokinetics

Cyanide is eliminated from the body by multiple pathways. The major route for detoxification of cyanide is the enzymatic conversion to thiocyanate. Two sulfurtransferase enzymes, rhodanese (thiosulfate-cyanide sulfurtransferase) and β -mercaptopyruvate-cyanide sulfurtransferase, catalyze this reaction. The primary pathway for metabolism is rhodanese, which is widely distributed throughout the body and has the highest concentration in the liver. This enzyme catalyzes the transfer of a sulfane sulfur from a sulfur donor, such as thiosulfate to cyanide to form thiocyanate. In acute poisoning, the limiting factor in cyanide detoxification by rhodanese is the availability of adequate quantities of sulfur donors. The endogenous stores of sulfur are rapidly depleted, and cyanide metabolism slows. Hence, the efficacy of sodium thiosulfate as an antidote stems from its normalization of the metabolic inactivation of cyanide. The sulfation of cyanide is essentially irreversible, and the sulfation product thiocyanate has relatively little inherent toxicity. Thiocyanate is eliminated in urine. A number of minor pathways of metabolism ($<15\%$ of total) account for cyanide elimination, including conversion to 2-aminothiazoline-4-carboxylic acid, incorporation into the 1-carbon metabolic pool, or in combination with hydroxycobalamin to form cyanocobalamin.

Limited human data regarding the cyanide elimination half-life are available. Elimination appears to follow first-order kinetics,⁷³ although it varies widely in reports (range 1.2–66 hours).^{8,51,73} Disparity in values may result from the number of samples used to perform calculations and the effects of antidotal treatment. The volume of distribution of the cyanide anion varies according to species and investigator, with 0.075 L/kg reported in humans.³⁴

Pathophysiology

Cyanide is an inhibitor of multiple enzymes, including succinic acid dehydrogenase, superoxide dismutase, carbonic anhydrase, and cytochrome oxidase.^{80,87} Cytochrome oxidase is an iron containing metalloenzyme essential for oxidative phosphorylation and, hence, aerobic energy production. It functions in the electron transport chain within mitochondria, converting catabolic products of glucose into adenosine triphosphate (ATP). Cyanide induces cellular hypoxia by inhibiting cytochrome oxidase at the cytochrome a_3 portion of the electron transport chain (Fig. 126–2).^{95,128} Hydrogen ions that normally would have combined with oxygen at the terminal end of the chain are no longer incorporated. Thus, despite

sufficient oxygen supply, oxygen cannot be utilized, and ATP molecules are no longer formed.⁷⁸ Unincorporated hydrogen ions accumulate, contributing to acidemia.

FIGURE 126–2. Pathway of cyanide and hydrogen sulfide toxicity and detoxification.

Hyperlactemia occurs following cyanide poisoning because of failure of aerobic energy metabolism. During aerobic conditions, when the electron transport chain is functional, lactate is converted to pyruvate by mitochondrial lactate dehydrogenase. In this process, lactate donates hydrogen moieties that reduce nicotinamide adenine dinucleotide (NAD^+) to NADH. Pyruvate then enters the tricarboxylic acid cycle, with resulting ATP formation. When cytochrome a_3 within the electron transport chain is inhibited by cyanide, there is a relative paucity of NAD^+ and predominance of NADH, favoring the reverse reaction, in which pyruvate is converted to lactate.

Cyanide is also a potent neurotoxin. Cyanide exhibits a particular affinity for regions of the brain with high metabolic activity. Central nervous system (CNS) injury occurs via several mechanisms, including impaired oxygen utilization, oxidant stress, and enhanced release of excitatory neurotransmitters. Cranial imaging of survivors of cyanide poisoning reveals that injury occurs in the most oxygen-sensitive areas of the brains, such as the basal ganglia, cerebellum, and sensorimotor cortex.

Cyanide enhances N-methyl-D-aspartate (NMDA) receptor activity and directly activates the NMDA receptor, which increases release of glutamate and inhibits voltage-dependent magnesium blockade of the NMDA receptor. This NMDA receptor stimulation results in Ca^{2+} entry into the cytosol of neurons. Cyanide also activates voltage-sensitive calcium channels⁶⁴ and mobilizes Ca^{2+} from intracellular stores.^{81,98} As a result, cytosolic Ca^{2+} rises and activates a series of biochemical reactions that lead to the generation of reactive oxygen species and nitrous oxide.^{70,84,106} These reactive oxygen species initiate peroxidation of cellular lipids, which, together with cyanide-induced inhibition of the respiratory chain, adversely affect mitochondrial function, initiating cytochrome c release and execution of apoptosis, necrosis, and subsequent neurodegeneration.^{6,64,97,107} Experimental studies demonstrate that NMDA inhibitors such as dextrorphan and dizocilpine, antioxidants, and cyclooxygenase inhibitors all protect neurons against cyanide-induced damage.^{61,77,125}

Sulfurtransferase metabolism via rhodanese is crucial for detoxification. However, the aforementioned cyanide-induced metabolic derangement may decrease enzyme detoxification. Decreased ATP and reactive oxygen species and increased cytosolic Ca^{2+} stimulate protein kinase C activity, which in turn inactivates rhodanese.³

Clinical Manifestations

Acute Exposure to Cyanide. The amount, duration of exposure, route of exposure, and premorbid condition of the individual influence the time to onset and severity of illness. A critical combination of these factors overwhelms endogenous detoxification pathways, allowing cyanide to diffusely affect cellular function within the body. No reliable pathognomonic symptom or toxic syndrome is associated with acute cyanide poisoning.⁴⁷ The initial clinical effects of acute cyanide poisoning may be nonspecific, generalized, and nondiagnostic, thereby making the correct diagnosis difficult to obtain. Clinical manifestations reflect rapid dysfunction of oxygen-sensitive organs, with central nervous and cardiovascular findings predominating. The time to onset of symptoms typically is seconds with inhalation of gaseous HCN or intravenous injection of a water soluble cyanide salt and several minutes following ingestion of an inorganic cyanide salt. The clinical effects of cyanogenic chemicals often are delayed, and the time course varies among individuals (ranging from 3–24 hours), depending on their rate of biotransformation.¹¹⁵ Clinically apparent cyanide toxicity may occur within hours to days of initiating nitroprusside infusion, although concurrent administration of thiosulfate or hydroxocobalamin may prevent toxicity (Chap. 63).¹⁰⁴

CNS signs and symptoms are typical of progressive hypoxia and include headache, anxiety, agitation, confusion,

lethargy, nonreactive dilated pupils seizures, and coma. A centrally mediated tachypnea occurs initially, followed by bradypnea and apnea.

Cardiovascular responses to cyanide are complex. Studies of isolated heart preparations and intact animal models show that the principal cardiac insult is slowing of rate and loss of contractile force.⁷ Several reflex mechanisms, including catecholamine release and central vasomotor activity, may modulate myocardial performance and vascular response in patients with cyanide poisoning.⁷¹ In laboratory investigations, a brief period of increased inotropy caused by reflex compensatory mechanisms occurs before myocardial depression. Clinically, an initial period of tachycardia and hypertension may occur, followed by hypotension with reflex tachycardia, but the terminal event is consistently bradycardia and hypotension. Ventricular dysrhythmias do not appear to be an important factor.

Pulmonary edema may be found at necropsy.⁴⁷ Inhalation of HCN may be associated with mild corrosive injury to the respiratory tract mucosa.

Gastrointestinal toxicity may occur following ingestion of inorganic cyanide and cyanogens and includes abdominal pain, nausea, and vomiting. These symptoms are caused by hemorrhagic gastritis, which is frequently identified on necropsy, and are thought to be secondary to the corrosive nature of cyanide salts. However, if death occurs rapidly, this gastritis may not be seen at autopsy because development of inflammation occurs over time.⁴⁷ Following ingestion, a smell of bitter almonds should not be relied upon to be emitted from the gastrointestinal system as health care providers in nearly all case reports published do not mention this finding.⁶³

Cutaneous manifestations may vary. Traditionally, a cherry-red skin color is described as a result of increased venous hemoglobin oxygen saturation, which results from decreased utilization of oxygen at the tissue level. This phenomenon may be more evident on fundoscopic examination, where veins and arteries may appear similar in color. Despite the inference in the name, cyanide does not directly cause cyanosis. The occurrence of cyanosis is commonly reported in published case reports and is likely due to cardiovascular collapse and subsequent poor perfusion.¹²²

Delayed Clinical Manifestations of Acute Exposure. Survivors of serious, acute poisoning may develop delayed neurologic sequelae. Parkinsonian symptoms, including dystonia, dysarthria, rigidity, and bradykinesia, are most common. Symptoms typically develop over weeks to months, but subtle findings can be present within a few days. Head computerized tomography and magnetic resonance imaging consistently reveal basal ganglia damage to the globus pallidus, putamen, and hippocampus, with radiologic changes appearing several weeks after onset of symptoms. Whether delayed manifestations result from direct cellular injury or secondary hypoxia is unclear. Extrapyrarnidal manifestations may progress or resolve. Response to pharmacotherapy with antiparkinsonian agents is generally disappointing

Chronic Exposure to Cyanide. Chronic exposure to cyanide may result in insidious syndromes, including tobacco amblyopia, tropical ataxic neuropathy, and Leber hereditary optic neuropathy. Tobacco amblyopia is a progressive loss of visual function that occurs almost exclusively in men who smoke cigarettes. Affected smokers have lower serum cyanocobalamin and thiocyanate concentrations than unaffected smoking counterparts, suggesting a reduced ability to detoxify cyanide. Cessation of smoking and administration of hydroxocobalamin often reverses symptoms. Tropical ataxic neuropathy is a demyelinating disease associated with improperly processed cassava consumption.^{91,112} Neurologic manifestations include Parkinson disease, spastic paraparesis, sensory ataxia, optic atrophy, and sensorineural hearing loss.¹²² Concomitant dermatitis and glossitis suggest an association of high dietary cassava with low vitamin B₁₂ intake. Elevated thiocyanate concentrations in affected individuals further implicate cyanide as the etiology. Removal of dietary cassava and institution of vitamin B₁₂ therapy alleviates symptoms. Leber hereditary optic atrophy, a condition of subacute visual failure affecting men, is thought to be caused by rhodanese deficiency⁴²

Chronic exposure to cyanide is associated with thyroid disorders.¹ Thiocyanate is a competitive inhibitor of iodide entry into the thyroid, thereby causing the formation of goiters and the development of hypothyroidism. Chronic exposure to cyanide in animals is associated with hydropic degeneration in hepatocytes and epithelial cells of the renal proximal tubules; however, these morphologic lesions are not linked to functional alternations.¹¹¹

Diagnostic Testing

Because of nonspecific symptoms and delay in laboratory cyanide confirmation, the clinician must rely on historical circumstances and some initial findings to raise suspicion of cyanide poisoning and institute therapy (Table 126–1).

TABLE 126–1. Cyanide Poisoning: Emergency Management Guidelines

When to suspect cyanide

Sudden collapse of laboratory or industrial worker

Fire victim with coma or academia

Suicide with unexplained coma or academia

Ingestion of artificial nail remover

Ingestion of seeds or pits from Prunus species

Patient with altered mental status, acidemia, and tachyphylaxis to nitroprusside

Supportive care

Control airway, ventilate, and give 100% oxygen

Crystalloids and vasopressors for hypotension

Administer sodium bicarbonate; titrate according to ABG and serum HCO_3^-

Antidotes

1) Hydroxocobalamin

Initial adult dose: 5 g IV over 15 minutes; pediatric dose 70 mg/kg up to 5 g

or

2) Cyanide Antidote Kit

Amyl nitrite pearls are included in the kit for prehospital use. For hospital management, sodium nitrite is the preferred methemoglobin inducer and is given in lieu of the pearls.

Give sodium nitrite (NaNO_2) as a 3% solution over 2–4 minutes IV: Adult dose: 10 mL (300 mg)

Caution: Monitor blood pressure frequently, and treat hypotension by slowing infusion rate and giving crystalloids and vasopressors. Obtain methemoglobin level 30 minutes after dose, and consider possible excessive methemoglobin formation if patient deteriorates during therapy. Withhold nitrites if COHb is suspected to be present.

Give sodium thiosulfate (NaS_2O_3) as a 25% solution IV:

Adult dose: 50 mL (12.5 g)

Pediatric dose: 1.65 mL/kg up to 50 mL

Decontamination

Protect health care provider from contamination

Cutaneous: Carefully remove all clothing and flush the skin

Ingestion: Oro- or nasogastric lavage and instill 1 g/kg activated charcoal

Laboratory

Arterial blood gas

Electrolytes and glucose

Blood lactate

Whole-blood cyanide concentration (for later confirmation only)

Laboratory findings suggestive of cyanide poisoning reflect the known metabolic abnormalities, which include metabolic acidosis, elevated lactate concentration, and increased anion gap. Elevated venous oxygen saturation results from reduced tissue extraction.⁶⁵ A venous oxygen saturation >90% from superior vena cava or pulmonary artery blood indicates decreased oxygen utilization. This finding is not specific for cyanide and could represent cellular poisoning from other

agents such as carbon monoxide, clenbuterol, hydrogen sulfide, and sodium azide, or medical conditions such as sepsis high-output cardiac syndromes and left to right intracardiac shunts.

Hyperlactatemia is found in numerous critical illnesses and typically is a nonspecific finding. However, a significant association exists between blood cyanide and serum lactate concentrations.^{9,10} ABG analysis of whole blood may provide additional information. Arterial pH correlates inversely with cyanide concentration.¹⁰ The finding of a narrow arterial–venous oxygen difference also may suggest cyanide toxicity.

Cyanide results in nonspecific electrocardiographic (ECG) findings.⁴⁰ Rhythm disturbances such as sinus tachycardia, bradydysrhythmias, atrial fibrillation, ventricular tachycardia, and ventricular fibrillation are all reported, as are elevation or depression of the ST segment, shortened ST segments, and fusion of the T wave into the QRS complex.

Blood cyanide concentration determination can confirm toxicity, but this determination is not available in a sufficiently rapid manner to affect initial treatment. Whole blood or serum can be analyzed, with most reports utilizing whole blood for cyanide detection. In mammals, including primates, whole-blood concentrations are twice serum concentrations as a result of cyanide sequestration in red blood cells. Background whole-blood concentrations in nonsmokers range between 0.02 and 0.5 µg/mL.^{52,59} Higher blood concentrations suggest toxicity. Coma and respiratory depression are associated with whole blood concentrations >2.5 µg/mL and death with concentrations >3 µg/mL. Detecting urinary cyanide is difficult, and urinary thiocyanate is a more readily detectable and useful marker of cyanide exposure. Serum thiocyanate concentrations are of little value in assessing patients with acute poisoning because of little correlation with symptoms but are useful in confirming exposure.

A semiquantitative assay that uses calorimetric paper test strips may immediately detect cyanide. Cyantesmo test strips currently are used by water treatment facilities to detect cyanide. An investigation of the utility of these strips in clinical practice found that the test strips incrementally increased to a deep blue color over a progressively longer portion of the test strip with increasing concentrations of cyanide in the blood.¹⁰² These strips accurately and rapidly detected, in a semiquantifiable manner, CN concentrations >1 µg/mL.

Management

Because cyanide poisoning is rare, it is easy to overlook the diagnosis unless there is an obvious history of exposure. Thus, the most critical step in treatment is considering the diagnosis in high-risk situations (Table 126–1) and initiating empiric therapy with 100% oxygen and either hydroxycobalamin or the cyanide antidote kit. The initial care (Table 126–1) of the cyanide-poisoned patient begins by directing attention to airway patency, ventilatory support, and oxygenation. Acidemia should be treated with adequate ventilation and sodium bicarbonate administration.

Intravenous access should be rapidly obtained and blood samples sent for renal function, glucose, and electrolyte determinations. A whole-blood cyanide concentration can be obtained for later confirmation of exposure. ABG analysis and serum lactate concentration will help assess acid–base status. Initiation of crystalloid and infusion of vasopressor for hypotension are warranted.

First responders should exercise extreme caution when entering potentially hazardous areas such as chemical plants and laboratories where a previously healthy person is “found down.” Exposure to cyanide may occur by multiple routes, including ingestion, inhalation, dermal, and parenteral. For patients with inhalation exposure, removal from the area of exposure is critical. Further decontamination is generally unnecessary. Decontamination of the cyanide-poisoned patient occurs concurrently with initial resuscitation. The health care provider should always be protected from potential dermal contamination by using personal protective devices such as water-impervious gowns, gloves, and eyewear. For patients with cutaneous exposure, remove their clothing, brush any powder off the skin, and flush the skin with water. Particular attention should be given to open wounds because CN[−] or HCN is readily absorbed through abraded skin.

Instillation of activated charcoal often is considered ineffective because of low binding of cyanide (1 g activated charcoal only adsorbs 35 mg cyanide). However, a potentially lethal oral dose of cyanide (ie, a few hundred milligrams) is within the adsorptive capacity of a typical 1 g/kg dose of activated charcoal. Prophylactic activated charcoal administration improved survival in animals given an LD₁₀₀ dose of KCN.⁷⁴ Based on the potential benefits and minimal risks, activated charcoal may be considered in the patient with an intact protected airway.

Although either hydroxocobalamin or the cyanide antidote kit can be administered as soon as cyanide poisoning is suspected, hydroxocobalamin is preferred. Hydroxocobalamin is a metalloprotein with a central cobalt atom that complexes cyanide, forming cyanocobalamin (vitamin B₁₂). Cyanocobalamin is eliminated in the urine or releases the cyanide moiety at a rate sufficient to allow detoxification by rhodanese. One molecule of hydroxocobalamin binds one molecule of cyanide, yielding a molecular weight binding ratio of 50:1. The US-approved adult starting dose is 5 g administered by intravenous infusion over 15 minutes. Depending upon the severity of the poisoning and the clinical response, a second dose of 5 g may be administered by intravenous infusion for a total dose of 10 g. Hydroxocobalamin has few adverse effects, which include allergic reaction and a transient reddish discoloration of the skin, mucous membranes, and urine.^{25,21,53} No hemodynamic adverse effects other than a potential mild transient rise of blood pressure are

observed^{16,105} (Antidotes in Depth: A41).

The cyanide antidote kit contains amyl nitrite, sodium nitrite, and sodium thiosulfate. Both thiosulfate and nitrite individually have antidotal efficacy when given alone in animal models of cyanide poisoning, but they have even greater benefit when they are given in combination.⁸⁰ Thiosulfate donates the sulfur atoms necessary for rhodanese-mediated cyanide biotransformation to thiocyanate. The mechanism of nitrite is less clear. Traditional rationale relies on the ability of nitrite to generate methemoglobin. Because cyanide has a higher affinity for methemoglobin than for cytochrome a_3 , cytochrome oxidase function is restored. However, improved hepatic blood flow and nitric oxide formation are alternate explanations (Antidotes in Depth: A39 and A40). Amyl nitrite is contained within glass pearls that are crushed and intermittently inhaled or intermittently introduced into the ventilator system to initiate methemoglobin formation. The amyl nitrite pearls are reserved for cases where intravenous access is delayed or not possible. Intravenous sodium nitrite is preferred and is supplied as a 10-mL volume of 3% solution (300 mg). Adverse effects of nitrites include excessive methemoglobin formation and, because of potent vasodilation, hypotension and tachycardia. Avoiding rapid infusion, monitoring blood pressure, and adhering to dosing guidelines will limit adverse effects. Because of the potential for excessive methemoglobinemia during nitrite treatment, pediatric dosing guidelines are available (Table 126–2). Sodium thiosulfate is the second component of the cyanide antidote kit. It is supplied as 50 mL of 25% solution (12.5 g). It is a substrate for the reaction catalyzed by rhodanese that is essentially irreversible, converting a highly toxic entity to a relatively harmless compound. However, thiocyanate does have its own toxicity in the presence of kidney failure, including abdominal pain, vomiting, rash, and CNS dysfunction. Thiosulfate itself is not associated with significant adverse reactions. The pediatric dose of thiosulfate is adjusted for weight.

TABLE 126–2. Cyanide Management: Pediatric Sodium Nitrite Guidelines^a

Hemoglobin (g)	NaNO ₂ (mg/kg)	3% NaNO ₂ solution (mL/kg)
7.0	5.8	0.19
8.0	6.6	0.22
9.0	7.5	0.25
10.0	8.3	0.27
11.0	9.1	0.30
12.0	10.0	0.33
13.0	10.8	0.36
14.0	11.6	0.39

^aPediatric thiosulfate dose: 1.65 mL/kg of 25% solution up to 50 mL.

Adapted, with permission, from Berlin CM: The treatment of cyanide poisoning in children. *Pediatrics*. 1970;46:793–796.

In Europe, 4-dimethylaminophenol (4-DMAP), rather than sodium nitrite, is the methemoglobin-inducer of choice.⁵⁴ It generates methemoglobin more rapidly than sodium nitrite, with peak methemoglobin concentrations at 5 minutes after 4-DMAP rather than 30 minutes after sodium nitrite. The dose of 4-DMAP is 3 mg/kg and is coadministered with thiosulfate. As with sodium nitrite, its major adverse effect is excessive methemoglobin formation and potential for hypotension. Cobalt in the form of dicobalt edetate has been used as a cyanide chelator, but its usefulness is limited by serious adverse effects such as hypotension, cardiac dysrhythmias, decreased cerebral blood flow, and angioedema.^{22,86} The cobalamin precursor cobinamide has been used both prophylactically and therapeutically to treat experimental cyanide toxicity, and when given at high enough doses, it has rescued animals from cyanide-induced apnea and coma.²³ Cobalamin has been used in France to treat human cyanide exposure, either alone or combined with sodium thiosulfate. Cobinamide is an investigational treatment that has a much greater affinity for cyanide ion than cobalamin.²⁹ Hyperbaric oxygen has been considered in the past, but recent evidence suggests no benefit in cyanide poisoning.⁷⁶

In animal models, the antioxidant vitamins A, C, and E diminish the extent of tissue damage caused by subacute cyanide intoxication.⁸⁹ This is especially important in the tropics, where the majority of dietary staples are cyanophoric crops such as cassava.

Patients who do not survive cyanide poisoning are suitable organ donors. Heart, liver, kidney, pancreas, cornea, skin, and bone have been successfully transplanted following cyanide poisoning.⁴¹

HYDROGEN SULFIDE POISONING

History and Epidemiology

Hydrogen sulfide (H_2S) exposures are often dramatic and can be fatal. The American Association of Poison Control Centers' National Poison Data System reported 5383 exposures from 2007 through 2011 (Chap. 136). Only 1534 of these exposures required evaluation at a health care facility, 457 reported moderate or major effects, and 36 deaths occurred.²⁴ Over a 10 year period from 1983 to 1992, 5563 exposures and 29 deaths attributed to hydrogen sulfide were reported in the National Poison Data System.¹¹⁰ Most often, serious consequences of hydrogen sulfide exposures occur through workplace exposures, but they can also occur in environmental disasters and most recently in suicides.

Bacterial decomposition of proteins generates hydrogen sulfide, and the gas is produced in many industrial activities. Decay of the sulfur-containing products such as fish, sewage, and manure produce hydrogen sulfide. Industrial sources include pulp paper mills, heavy-water production, the leather industry, roofing asphalt tanks, vulcanizing of rubber, viscose rayon production, and coke manufacturing from coal.³¹ It is a major industrial hazard in oil and gas production, particularly in sour gas fields (natural gas containing sulfur).

Between 1990 and 1999, hydrogen sulfide poisoning was associated with the deaths of 18% of US construction workers killed by toxic inhalation.³⁵ Many died while working in confined spaces such as sewers or sewer manholes. Agricultural workers operating near livestock manure storage tanks are at greatest risk of harm from an inhalation exposure.^{12,55} Poisoned workers are “knocked down,” prompting coworkers to attempt a rescue. Numerous case reports describe multiple victims because the would-be rescuers often themselves become victims when they attempt a rescue in an environment having high concentrations of hydrogen sulfide.^{12,35,55} Studies report that up to 25% of fatalities involve rescuers.^{35,44,58}

OSHA and a variety of occupational organizations such as the American Industrial Hygiene Association, the National Institute of Occupational Safety and Health, the American Shipbuilding Association, and the US Chemical Safety Board recognize the serious dangers of hydrogen sulfide exposures in the workplace and continue to promote safety alerts and educational programs.⁹³

Natural sources of hydrogen sulfide are volcanoes, caves, sulfur springs, and underground deposits of natural gas.^{31,101} Hydrogen sulfide is also implicated in several environmental disasters. In 1950, 22 people died and 320 were hospitalized in Poza Rica, Mexico, when a local natural gas facility inadvertently released hydrogen sulfide into the air.⁸² Hydrogen sulfide claimed nine lives when a sour gas well failed, releasing a cloud of the poisonous gas into the Denver City, Texas community in 1975.⁸⁵ In 2003, a gas drilling incident in southwest China released natural gas and a cloud of hydrogen sulfide into a populated area, killing more than 200 people, injuring 9000, and necessitating the evacuation of more than 40,000.¹²⁹

Recently, a large number of suicides called “chemical suicides” or “detergent suicides” have been attributed to mixing common household chemicals such as pesticides or fungicides and toilet bowl cleaners to create hydrogen sulfide gas.^{116,119} This practice is of concern because the recipes are easily found on Internet sites, precursor chemicals are readily accessible from the cleaning section of many local stores, first responders are at risk of harmful toxic effects from exposure, and the toxic gas can inadvertently expose groups of people in nearby buildings. In Japan, it is reported that more than 500 people killed themselves in the first half of 2008 by this means.¹³⁰ Information resources on the Internet are implicated for the widespread practice and prompted police to request purging the suicide recipes from Internet sites.⁵⁶ In the United States, chemical suicides from hydrogen sulfide are likely underreported but rose from 2 in 2008 to 19 in 2010.¹⁰⁰ In as many as 80% of incidents, first responders report exposures following attempted rescue of victims.¹⁰⁰ Suicide victims using this method to harm themselves inadvertently cause injuries and evacuations because of the toxic gas permeating buildings. One incident in Japan caused 90 people to become ill from the toxic gas as it permeated an apartment building, and another resulted in 350 people evacuating a building.¹¹⁹

Pharmacology and Toxicokinetics

Hydrogen sulfide is a colorless gas, more dense than air, with an irritating odor of “rotten eggs.” It is highly lipid soluble, a property that allows easy penetration of biologic membranes. Systemic absorption usually occurs through inhalation, and it is rapidly distributed to tissues.¹⁰¹

The tissues most sensitive to hydrogen sulfide are those with high oxygen demand. The systemic toxicity of hydrogen sulfide results from its potent inhibition of cytochrome oxidase, thereby interrupting oxidative phosphorylation.³¹ Hydrogen sulfide binds to the ferric (Fe^{3+}) moiety of cytochrome a_3 oxidase complex with a higher affinity than does cyanide. The resulting inhibition of oxidative phosphorylation produces cellular hypoxia and anaerobic metabolism.^{31,131}

Cytochrome oxidase inhibition is not the sole mechanism of toxicity. Other enzymes are inhibited by hydrogen sulfide and may contribute to its toxic effects.¹⁰¹ Besides producing cellular hypoxia, hydrogen sulfide alters brain neurotransmitter release and transmission through potassium channel-mediated hyperpolarization of neurons, potentiate NMDA receptors,

and other neuronal inhibitory mechanisms.^{90,101} A proposed mechanism of death is poisoning of the brainstem respiratory center through selective uptake by lipophilic white matter in this region.¹²⁷ The olfactory nerve is a specific target of great interest. Not only does the toxic gas cause olfactory nerve paralysis, but it is thought to be a portal of entry into the central nervous system because of its direct contact with the brain.¹³¹ It is also cytotoxic through formation of reactive sulfur and oxygen species. It may also react with iron to fuel the Fenton reaction causing free radical injury¹¹⁷ (Chaps. 12 and 13).

In addition to systemic effects, hydrogen sulfide reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. The eyes and nasal and respiratory mucous membranes are the tissues most susceptible to direct injury.^{75,131} Despite skin irritation, it has little dermal absorption.

Along with nitric oxide and carbon monoxide, researchers recently recognized hydrogen sulfide as a signaling molecule of the cardiovascular, inflammatory, and nervous systems, and therefore, they proposed to add hydrogen sulfide as the “third endogenous gaseous transmitter.” In 2005, a report in *Science* demonstrated mice inhaling a low dose of hydrogen sulfide, which decreased their metabolic demands and caused them to enter a “suspended animationlike state.”¹⁸ This report propelled researchers into studies probing the biosynthesis, metabolism, and physiological responses of hydrogen sulfide in hopes of developing future beneficial therapies to combat the adverse consequences of ischemia/reperfusion injury.^{37,90} The research results reveal fascinating and sometimes puzzling and contradictory results. Administering hydrogen sulfide to rodents appears to switch off metabolic demands and protect some species from ischemic insults. On the contrary, large animal models have yet to show global protection but support local, organ-specific protective effects. In total, these studies reveal hydrogen sulfide to have complex interactions that are variable among organ systems and species while clearly demonstrating a dose-dependent effect with higher exposures producing the well-known toxic effects. Besides its ability to attenuate metabolic demands during ischemia, hydrogen sulfide influences many signaling pathways and has vasodilating, neuromodulating, antiinflammatory, antiapoptotic, and antioxidant effects. Using hydrogen sulfide as a therapy requires additional investigation, but several hydrogen sulfide donating drugs are already in clinical trials.⁷⁹ Researchers’ enthusiastic pursuit of a better understanding of hydrogen sulfide with an intent to create innovative therapies will likely also benefit our understanding of its mechanisms of toxicity and potentially lead to new treatments for toxic exposures.

Inhaled hydrogen sulfide enters the systemic circulation where it dissociates into hydrosulfide ions (HS^-), sulfide (S^{2-}), and sulfate (SO_4^{2-}). Once dissociated, hydrosulfide ions interact with metalloproteins, disulfide containing enzymes, and thio dimethyl S transferase.³² Hydrogen sulfide and dissociation products are then rapidly metabolized by oxidation, methylation, and binding to metalloproteins. The major pathway of detoxification is enzymatic and nonenzymatic oxidation of sulfides and sulfur to thiosulfate and polysulfides.^{131,90} Other pathways, such as methylation to dimethyl sulfide and conversion to sulfite or sulfate by oxidized glutathione, also may play a role in detoxification and elimination.^{31,131} Sulhemoglobin is not found in significant concentrations in the blood of animals or fatally poisoned humans.^{90,96}

Clinical Manifestations

Acute Manifestations. Hydrogen sulfide poisoning should be suspected whenever a person is found unconscious in an enclosed space, especially if the odor of rotten eggs is noted. The primary target organs of hydrogen sulfide poisoning are those of the CNS and respiratory system. The clinical findings reported in two large series are listed in Table 126–3^{4,26}

TABLE 126–3. Hydrogen Sulfide Poisoning

When to suspect hydrogen sulfide poisoning

- Rapid loss of consciousness (“knocked down”)
- Rotten eggs odor
- Rescue from enclosed space, such as sewer or manure pit
- Multiple victims with sudden death syndrome
- Collapse of a previously healthy worker at work site

Clinical Manifestations

System	Signs and Symptoms
Cardiovascular	Chest pain, bradycardia, sudden cardiac arrest
Central nervous	Headache, weakness, syncope, convulsions, rapid onset of coma
Gastrointestinal	Nausea, vomiting
Ophthalmic	Conjunctivitis
Pulmonary	Dyspnea, cyanosis, crackles, apnea
Metabolic	Metabolic acidosis

Hydrogen sulfide poisoning has a distinct dose response, and the intensity of exposure likely accounts for the diverse clinical findings in the reports. The odor threshold is between 0.01 and 0.3 ppm, and a strong intense odor is noted at 20 to 30 ppm. Mild mucous membrane irritation occurs at 20 to 100 ppm. Olfactory nerve paralysis occurs at 100 to 150 ppm rapidly extinguishing the ability to perceive the gas odor at higher concentrations. Prolonged exposure can occur when the extinction of odor recognition is misinterpreted as dissipation of the gas. Strong irritation of the upper respiratory tract and eyes and ARDS occur at 150 to 300 ppm. At >500 ppm, hydrogen sulfide produces systemic effects. Rapid unconsciousness and cardiopulmonary arrest occur at concentrations >700 ppm. At 1000 ppm, breathing may cease after one to two breaths.^{11,49,101}

Hydrogen sulfide reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. Mucous membrane irritation of the eye produces keratoconjunctivitis. If exposure persists, damage to the epithelial cells produces reversible corneal ulcerations (“gas eye”) and, rarely, irreversible corneal scarring.^{75,123} The irritant effects on the respiratory tract include rhinitis, bronchitis, and ARDS.^{4,26,131}

Neurologic manifestations are common and may be severe. Hydrogen sulfide’s rapid and deadly onset of clinical effects have been termed the “slaughterhouse sledgehammer” effect. In one case series, 75% of 221 patients with acute hydrogen sulfide exposure lost consciousness at the time of exposure.²⁶ If the patient is rapidly removed from the exposure, recovery may be prompt and complete. Hypoxia from respiratory compromise can cause secondary neurologic effects.^{11,31,131,50} Neurologic outcome can be quite variable, ranging from no neurologic impairment to permanent sequelae. Delayed neuropsychiatric sequelae may occur after acute exposures.²⁷ Most evidence suggests that the early rapid CNS effects are direct neurotoxic effects of hydrogen sulfide, whereas the permanent neurologic sequelae result from hypoxia secondary to respiratory insufficiency.^{11,131} Reported neuropsychiatric changes include memory failure (amnesic syndrome), lack of insight, disorientation, delirium, and dementia.^{31,131} Neurosensory abnormalities include transient hearing impairment, vision loss, and anosmia. Motor symptoms are likely caused by injury to the basal ganglia and result in ataxia, position/intention tremor, and muscle rigidity.¹²⁰ Common neuropathologic findings observed on neuroimaging and at autopsy are subcortical white matter demyelination and globus pallidus degeneration.²⁷

Acute exposures also affect other organ systems. Myocardial hypoxia or direct toxic effects of hydrogen sulfide on cardiac tissue may cause cardiac dysrhythmias, myocardial ischemia, or myocardial infarction.⁴⁸ Because unresponsiveness is rapid, trauma from falls should not be overlooked.^{4,45} In a report, 7% of patients experiencing a “knockdown” had associated traumatic injuries.⁴

Chronic Manifestations. Most data about chronic low-level exposures to hydrogen sulfide come from oil and gas industry workers. Mucous membrane irritation seems to be the most prominent problem in patients with low-concentration exposures. Workers report nasal, pharyngeal, and eye irritation, fatigue, headache, dizziness, and poor memory with low-concentration, chronic exposures. The chronic irritating effects of hydrogen sulfide were thought to be the cause of reduced lung volumes observed in sewer workers.¹⁰³ Volunteer studies have not demonstrated significant cardiovascular effects after long term exposure to concentrations less than 10 ppm.¹⁷ The liver, kidneys, and endocrine system are unaffected. No studies demonstrate increased incidences of cancer with low-level exposures.³¹

Rapid loss of consciousness from hydrogen sulfide exposure was a well-known and, amazingly, accepted part of the workplace in the gas and oil industry for many years.⁶⁰ Some workers experienced repeated “knockdowns,” and these workers reported an increased incidence of respiratory diseases and cognitive deficits. Single or repeated high-

concentration exposures resulting in unconsciousness can cause serious cognitive dysfunction. The acute effects of rapid loss of consciousness are most likely due to hydrogen sulfide neurotoxicity. Although a clear association exists between knock-down and chronic neurologic sequelae, many of the case reports are complicated by associated apnea or hypoxemia from respiratory failure, asphyxia or exposure to other xenobiotics in a confined space, head injury from a fall, or near drowning in liquid manure or sludge.¹³¹ The association of neurotoxic sequelae are less clear with protracted low-concentration exposures. Case series suggest that low-concentration exposures can cause subtle changes that can be measured by only the most sensitive neuropsychiatric tests.⁷²

Epidemiologic data regarding the effects of low-concentration environmental exposures to hydrogen sulfide are clouded in populations exposed to complex mixtures of pollutants. Other malodorous sulfur compounds (eg, methyl mercaptan and methyl sulfide) are generated as byproducts of pulp mills. Study populations exposed to this complex mixture of pollutants demonstrate a dose-related increase in nasal symptoms, cough, nausea, and vomiting.³¹

These changes are nonspecific, and many of the cases have a poorly documented exposure assessment. Currently, the association of protracted and low-concentration hydrogen sulfide exposure with chronic neurological sequelae remains controversial and needs further study.^{50,131}

The strong odor of low concentrations of hydrogen sulfide can magnify irritant effects by triggering a strong psychological response.¹³¹ The odor of hydrogen sulfide at low levels has been the alleged source of mass psychogenic illness cases.⁴⁶ Clinical, epidemiologic, and toxicologic analyses suggested that 943 cases of illness in Jerusalem were caused by the odor of low concentrations of hydrogen sulfide gas. The most frequent associated symptoms are headaches; faintness; dizziness; nausea; chest tightness; dyspnea and tachypnea; eye, nose, and throat irritation; weakness; and extremity numbness. Low concentration exposure to hydrogen sulfide may produce nonspecific signs and symptoms that could closely mimic psychogenic illness. Attempting to identify true toxicity from a powerful emotional reaction can be extremely difficult.⁴⁶ Therefore, symptomatic patients must be assessed for toxicity even when mass psychogenic illness is suspected.

Diagnostic Testing

In hydrogen sulfide poisoning, diagnostic testing is of limited value for clinical decision making following acute exposures, confirmation of acute exposures, occupational monitoring, and forensic analysis following fatal accidents.

Clinicians must base management decisions on history, clinical presentation, and diagnostic tests that infer the presence of hydrogen sulfide because no method is available to rapidly and directly measure the gas or its metabolites. Circumstances surrounding the patient's illness often provide the best evidence for hydrogen sulfide poisoning (Table 126–3). At the bedside, the smell of rotten eggs on clothing or emanating from the blood, exhaled air, or gastric secretions suggests hydrogen sulfide exposure. In addition, darkening of silver jewelry is a clue to exposure. Paper impregnated with lead acetate changes color when exposed to hydrogen sulfide and is used to detect its presence in the patient's exhaled air but is not rapidly available.³¹

Specific tests for confirming hydrogen sulfide exposure are not readily available in clinical laboratories. Therefore, directly measuring the gas in atmospheric air samples by monitoring devices provides stronger evidence of hydrogen sulfide as the causative agent. Epidemiologic data show hydrogen sulfide as one of the most common causes of death and injury from toxic inhalation in confined spaces, especially manholes and sewers.³⁶ Recognizing confined spaces as extremely hazardous environments, OSHA published the Confined Space Entry Standard to protect workers.² It mandates training, rescue procedures, and atmospheric testing before entry, including measuring for the presence of hydrogen sulfide. Because of OSHA's regulations, most emergency response teams are equipped to investigate toxic environments from hazardous materials incidents using a "four-gas detection unit" that measures hydrogen sulfide by electrochemical sensors along with measurements for atmospheric oxygen concentration and the presence of explosive gases and carbon monoxide.¹²¹ In general, the clinician must interpret environmental detection results with caution. Toxic gases may dissipate prior to atmospheric air sample collection, leading to negative results, or interfering gases can trigger false positive readings on detection devices.⁵⁷ A positive reading on a field device does not equate to confirmation of that specific gas. Clinical decision making should consider correlation with other circumstantial and clinical data and not rely solely on detection results.

In acute poisoning, readily available diagnostic tests that are biomarkers of hydrogen sulfide poisoning may be useful but are nonspecific. ABG analysis demonstrating metabolic acidosis with an associated elevated serum lactate concentration is expected, and oxygen saturation should be normal unless ARDS is present. Hydrogen sulfide, like cyanide, decreases oxygen consumption and is reflected as an elevated mixed venous oxygen measurement. Because sulfhemoglobin typically is not generated in patients with hydrogen sulfide poisoning, an oxygen saturation gap is not expected.^{90,96}

After serious injury from hydrogen sulfide, diagnostic testing for neurologic structure and function may show abnormalities for weeks or months. Brain MRI and head CT studies demonstrate structural changes, such as globus pallidus degeneration and subcortical white matter demyelination. Neuropsychological testing after serious hydrogen sulfide poisoning demonstrates specific abnormalities in cortical functions, such as concentration, attention, verbal abstraction, and

short-term retention. Single-photon emission computed tomography (SPECT)/PET brain scans define neurotoxin-induced lesions that correlate well with clinical neuropsychological testing.²⁸

No clinically available biological markers or direct measurements of hydrogen sulfide and its metabolites exists, therefore, confirming poisoning is challenging for clinicians, researchers, and forensic specialists.⁹⁰ Whole blood sulfide concentrations >0.05 mg/L are considered abnormal. Reliable measurements are ensured only if the concentration is obtained within 2 hours after the exposure and analyzed immediately.¹⁰¹

In acute exposures, blood and urine thiosulfate concentrations may be reflective of exposure.⁶⁹ Urinary thiosulfate excretion may be useful to monitor chronic low-concentration exposure in the workplace. However, one study could not demonstrate a correlation between the degree of exposure and change in urine thiosulfate from baseline measurements.³⁸ Another study analyzed the value of blood and urine thiosulfate from data collected in case series of fatal and nonfatal hydrogen sulfide victims.^{66,68} Because thiosulfate was detected in the urine but sulfide and thiosulfate were not detected in the blood of nonfatal exposures, this report concluded that thiosulfate in urine is the only indicator to prove hydrogen sulfide poisoning in nonfatal cases.

Sulfide concentrations obtained in postmortem investigations may be useful, but their use requires rapid sample collection because sulfide concentrations rise with tissue decomposition.¹⁰¹ In addition to blood sulfide concentrations, sulfide and thiosulfate concentrations are at their highest in lung and brain.⁶⁷ If death is rapid, urinary thiosulfate concentrations may be nondetectable despite blood sulfide and thiosulfate concentrations 10-fold or greater than normal concentrations.⁶⁷ At autopsy, a greenish discoloration of the gray matter, viscera, and bronchial secretions may be noted.^{67,88}

Management

The initial treatment (Table 126–4) is immediate removal of the victim from the contaminated area into a fresh air environment. High-flow oxygen should be administered as soon as possible. Optimal supportive care has the greatest influence on the patient’s outcome. Because death from inhalation of hydrogen sulfide is rapid, limited human cases reaching the hospital for treatment are reported in the literature. Most patients experience significant delays before receiving treatment. Therefore, specific treatments and antidotal therapies do not show definitive improvement in patient outcome.

TABLE 126–4. Hydrogen Sulfide Poisoning: Emergency Management

Supportive care

Prehospital

Attempt rescue only if using appropriate respiratory protection

Move victim to fresh air

Administer 100% oxygen

During extrication, consider traumatic injuries from falls

Apply ACLS protocols as indicated

Emergency department

Maximize ventilation and oxygenation

Consider PEEP for ARDS

Treat metabolic acidosis based on arterial pH and serum bicarbonate analysis

Administer crystalloid and vasopressors for hypotension

Antidote

Give sodium nitrite (3% NaNO₂) IV over 2–4 minutes

Adult dose: 10 mL (300 mg)

Pediatric dose: See [Table 126–2](#); if hemoglobin unknown, presume 7 g Hb for dosing

Caution:

Monitor blood pressure frequently

Obtain methemoglobin level 30 minutes after dose

The proposed toxic mechanisms, animal studies, and human case reports suggest that oxygen therapy is beneficial for hydrogen sulfide poisoning.^{31,33,99,131} Proposed mechanisms for the beneficial effects of oxygen are competitive reactivation of oxidative phosphorylation by inhibiting hydrogen sulfide–cytochrome binding, enhanced detoxification by catalyzing oxidation of sulfides and sulfur, and improved oxygenation in the presence of ARDS. Recent studies demonstrate hydrogen sulfide’s binding to cytochrome oxidase is readily reversible in the presence of oxygen.³³ Other studies show an inverse relationship between tissue concentrations of hydrogen sulfide and oxygen.⁹⁰ Increased oxygen concentrations enhance the consumption of hydrogen sulfide through metabolic pathways, while oxygen deprivation results in the accumulation of hydrogen sulfide in tissue.⁹⁰ All patients suspected of hydrogen sulfide poisoning should receive supplemental oxygen. In case reports, poisoned patients receiving HBO had favorable clinical outcomes.^{5,62,109} However, no clinical data is available to suggest HBO is superior to normobaric oxygen for acute poisoning or preventing delayed neurological sequelae.

The similarities in the toxic mechanism between hydrogen sulfide and cyanide created an interest in the use of nitrite-induced methemoglobin as an antidote. Methemoglobin protects animals from toxicity of hydrogen sulfide poisoning in both pretreatment and postexposure treatment models. Nitrite-generated methemoglobin acts as a scavenger of sulfide. The affinity of hydrogen sulfide for methemoglobin is greater than that for cytochrome oxidase. When hydrogen sulfide binds to methemoglobin, it forms sulfmethemoglobin.¹⁵ Because hydrogen sulfide poisoning is rare, no studies have evaluated the clinical outcomes of patients treated with sodium nitrite. Animal studies suggest that nitrite must be given within minutes of exposure to ensure effectiveness.¹⁵ However, several human case reports showed rapid return of normal sensorium when nitrites were administered soon after exposure.^{62,94,114} Patients with suspected hydrogen sulfide poisoning who have altered mental status, coma, hypotension, or dysrhythmias should receive sodium nitrite by slow infusion at the same dose given for cyanide poisoning. Sodium thiosulfate is of no benefit in the treatment of hydrogen sulfide. In addition, only a single in vivo mouse model and a single case report with a fatal outcome is published to suggest a beneficial effect of hydroxocobalamin as an antidote for hydrogen sulfide poisoning.^{43,118} Additional research is warranted to determine its usefulness for hydrogen sulfide poisoning.

Treatment of patients with hydrogen sulfide poisoning requires optimal supportive care. Treatments and antidotes beyond supportive care are not of proven clinical benefit. Because hydrogen sulfide toxicity is severe and research studies suggest potential benefits of nitrite therapy, it should be considered for seriously ill patients exposed to hydrogen sulfide. This therapy should be initiated after optimum supportive care has been ensured.

Only a few inhalation risks are similar to hydrogen sulfide in their ability to rapidly “knock-down” victims. Some examples include low-oxygen environments in an enclosed space, hydrogen cyanide, volatile nerve agents, and carbon monoxide. The etiology may be unclear early in the patient’s emergency care and require clinicians to make treatment decisions without confirmatory evidence of poisoning. Clinicians faced with victims of “knock-down” syndrome should search for clues, such as victims’ activities (eg, working at a manure pit), reports of chemicals detected at the scene by first responders, or suggestive clinical signs. The critical decision is whether to administer specific antidotes empirically. Vapor exposure to volatile nerve agents would likely result in miosis and require antidotes such as atropine, pralidoxime, and benzodiazapines. Which cyanide antidotes to administer in a “knock-down” situation, if any, is most difficult. The basic aims are to gather as many facts and suggestive clues as possible, weigh the risk benefits for treatment or not, and treat early in the course. All this while meticulous attention to optimal supportive care is required.

SUMMARY

- Both cyanide and hydrogen sulfide are high risk xenobiotics.
- There are particular metabolic risks and concerns with regard to exposure to both xenobiotics because they bind specifically to the ferric moiety of the cytochrome a_3 oxidase complex.
- Odor recognition is unreliable and is not a definitive approach to diagnosis.
- The laboratory evaluation usually is not timely for diagnostic purposes.
- Decontamination, removal from the site of exposure, and oxygen are essential.

A39 ANTIDOTES IN DEPTH

Sodium and Amyl Nitrite

Mary Ann Howland

INTRODUCTION

Sodium nitrite is an effective cyanide antidote when administered in a timely fashion and followed by sodium thiosulfate, which acts in synergy. The utility of amyl nitrite, a volatile drug available in ampules that can be broken and administered by inhalation while sodium nitrite is being prepared to administer intravenously, is questioned.¹³ Although the exact mechanism of action of the nitrites is unclear, the production of methemoglobin is both therapeutic in cyanide poisoning and potentially life-threatening if nitrites are administered to a patient with impaired oxygen carrying capacity, from elevated concentrations of carboxyhemoglobin, methemoglobin, or sulfhemoglobin from any cause. In the latter cases, hydroxocobalamin and or sodium thiosulfate can still be administered intravenously without causing harm.

HISTORY

Expanding on earlier work that demonstrated the limited role of methylene blue and the efficacy of sodium nitrite in cyanide poisoned dogs, inhaled amyl nitrite prevented the development of cyanide-induced seizures and muscular rigidity.⁴ Amyl nitrite administered by inhalation protected dogs from up to four minimum lethal doses of sodium cyanide (a total of 24 mg/kg subcutaneously). In the regimen used, therapy was started within 5 to 7 minutes of exposure and was continued for several hours. The frequency of inhalation was based on clinical response. These experimental results led to the use of inhaled amyl nitrite for patients poisoned by cyanide. The same authors discovered that intravenous (IV) use of sodium thiosulfate alone protected against three minimum lethal doses of cyanide in dogs and that the combination of sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite protected against 10 to 18 minimum lethal doses, respectively.^{3,5}

PHARMACOLOGY

Chemistry

The chemical formula for sodium nitrite is NaNO_2 and for amyl nitrite is $\text{C}_5\text{H}_{11}\text{NO}_2$. Sodium nitrite has a molecular weight of 69 Da and amyl nitrite has a molecular weight of 117 Da. Amyl nitrite is volatile even at low temperatures and is highly flammable.

Cyanide quickly and reversibly binds to the ferric iron in cytochrome oxidase, inhibiting effective energy production throughout the body. The ferric iron in methemoglobin preferentially combines with cyanide, producing cyanomethemoglobin. This drives the reaction toward cyanomethemoglobin and liberates cyanide from cytochrome oxidase. Stroma-free methemoglobin is effective against four minimum lethal doses of cyanide in rats.²⁰ Nitrites oxidize the iron in hemoglobin to produce methemoglobin. Because nitrites are accepted antidotes for cyanide poisoning, for many years methemoglobin formation was assumed to be their sole antidotal mechanism of action.^{14,24} Other, faster methemoglobin inducers, such as 4-dimethylaniline and hydroxylamine, also are effective as cyanide antidotes.^{14,22} The production of methemoglobin by nitrite is slow, but when methylene blue is administered to prevent methemoglobin formation, nitrite remains an effective antidote.^{14,24} Reasoning that nitrite-induced vasodilation might be part of the mechanism of action, investigators considered the antidotal actions of other vasodilators. The α -adrenergic antagonists and ganglionic blockers only demonstrate antidotal activity when administered with sodium thiosulfate.²⁴ It is possible that the benefits of nitrites given shortly after cyanide result from reversal of cyanide-induced circulatory effects rather than reversal of the effects of cyanide on cytochrome oxidase.²¹ Experimental evidence in organ damage induced by hypoxia or hypotension suggests that the benefits of nitrite may be related to its conversion to nitric oxide, a potent vasodilator. The conversion to nitric oxide appears to occur only in tissues or blood with the lowest oxygen concentrations.^{6,15}

PHARMACOKINETICS AND PHARMACODYNAMICS

The pharmacokinetics of sodium nitrite are not established. Most studies were directed at measuring methemoglobin levels rather than nitrite concentrations.²²

Sodium nitrite administered intramuscularly to dogs is not effective as a cyanide antidote unless atropine is given as pretreatment.²³ Most likely the rapid reversal of cyanide-induced bradycardia by atropine allows sufficiently rapid absorption of sodium nitrite, which then can be effective.²³ In one study, 300 mg IV sodium nitrite produced peak methemoglobin levels of 10% to 18% in healthy adults, and values of 7% when 4 mg/kg was administered.^{3,17} Inhalation of crushed amyl nitrite ampules in human volunteers produces insignificant amounts of methemoglobin and causes headache, fatigue, dizziness, and hypotension.¹²

The package insert states that approximately 40% of sodium nitrite is renally eliminated unchanged, while the remainder is metabolized to ammonia and other related molecules.¹⁷

ROLE IN CYANIDE TOXICITY

Maximal benefits of sodium nitrite are realized experimentally when sodium nitrite is given prophylactically, but benefits are still evident even when sodium nitrite is administered following cyanide poisoning. Sodium nitrite is clearly effective soon after administration, even when methemoglobin levels are low. Thus a target methemoglobin concentration should not be used to determine the correct dose of sodium nitrite, although care must be taken to avoid excessive methemoglobinemia.¹¹ Administration of sodium nitrite should always be followed by sodium thiosulfate. Sodium thiosulfate donates a sulfur, which, with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfurtransferase, carries sulfane sulfur to bind to cyanide, producing thiocyanate. Thiocyanate is a much less toxic substance than cyanide and is renally eliminated.⁴

As early as 1952, the literature reported 16 cyanide-poisoned patients who survived following administration of nitrites and sodium thiosulfate.³ Even patients who were unconscious or apneic survived when given timely cardiopulmonary resuscitation and antidotal therapy.³ Case reports attest to the ability of amyl nitrite, sodium nitrite, and sodium thiosulfate to reverse the effects of cyanide if they are administered in a timely fashion.^{8,25} A 34 year-old man who ingested 1 g potassium cyanide became comatose within 45 minutes. One hour after ingestion, he arrived in the emergency department, became apneic, and was intubated. His blood pressure was 134/84 mm Hg and pulse 84 beats/min with fixed and dilated pupils. At 1 hour 15 minutes, he was given 300 mg sodium nitrite intravenously over 20 minutes, followed by 12.5 g sodium thiosulfate. Seizure activity that began just prior to sodium nitrite infusion resolved rapidly, and by the time the sodium thiosulfate was infused, his pupils were reactive and spontaneous respirations had returned.⁸

In another case, a 4 year-old boy ingested twelve 50 mg tablets of laetrile (amygdalin), became unresponsive, and developed seizures within 90 minutes.¹⁰ Upon arrival at a second hospital, the patient required intubation, had no blood pressure, and had dilated minimally responsive pupils. Arterial blood gas analysis revealed: pH, 6.85; PCO₂, 15 mm Hg; PO₂, 169 mm Hg on 100% oxygen with an anion gap of 26 mEq/L. His vital signs improved with intermittent inhalation of amyl nitrite pearls. Six hours after ingestion (and 1 hour 45 minutes after amyl nitrite administration), sodium nitrite and sodium thiosulfate obtained from another hospital were administered. Within 30 minutes of completion of 5 mL (0.33 mL/kg) 3% sodium nitrite solution by IV infusion, spontaneous respirations returned, and his blood pressure and pulse normalized. Over the next 3 hours, his mental status and acid-base status improved. Fifteen hours after ingestion, he was alert, oriented, and extubated. Elevated whole blood cyanide concentrations verified the ingestion.

A study in swine evaluated the effect of hydroxocobalamin plus sodium thiosulfate versus sodium nitrite and sodium thiosulfate in a model utilizing a continuous infusion of cyanide. There was no difference between the groups in metabolic acidosis with elevated lactate concentrations at times 20 and 40 minutes or in cardiac output and pulse rate at 40 minutes, or in mortality. The mean arterial pressure was higher in the hydroxocobalamin plus sodium thiosulfate group, beginning at 5 minutes and lasting for the entire 40 minute monitoring period.¹

ADVERSE EFFECTS AND SAFETY ISSUES

Amyl nitrite and sodium nitrite may work in part by inducing methemoglobinemia, but excessive methemoglobinemia is potentially lethal. Therefore, nitrite dosages must be carefully calculated to avoid excessive methemoglobinemia, especially in cases where other coexisting conditions, such as carboxyhemoglobin, sulfhemoglobin, and anemia, might compromise hemoglobin oxygen saturation.^{9,16} Children are particularly at risk for medication errors because of dosage miscalculations. A reported death from methemoglobinemia was caused by the administration of an adult dose of sodium nitrite to a 17 month-old child suspected of ingesting a toxic amount of cyanide.²

Nitrites are potent vasodilators, resulting in transient hypotension. Other common adverse effects include headache,

tachycardia, palpitations, dysrhythmia, blurred vision, nausea, and vomiting.^{3,17}

PREGNANCY AND LACTATION

The nitrites are FDA Pregnancy Category C. There are no adequate studies in pregnant women, and nitrites should only be used in pregnant women when the potential benefit exceeds the potential risk. Sodium nitrite has caused fetal death in humans as well as animals.¹⁷ The fetus is particularly sensitive to methemoglobinemia with the potential for prenatal hypoxia. High concentrations of nitrites in maternal drinking water have led to teratogenic effects.

Hydroxocobalamin is also FDA Pregnancy Category C; however, even with the limited data available it may have a lesser risk than nitrite use for a pregnant woman.⁷

It is not known whether nitrites are excreted in breast milk, but the risk is likely to exceed the benefit.

DOSING AND ADMINISTRATION

Adults

Sodium nitrite 300 mg (10 mL of 3% solution) should be injected intravenously at a rate of 2.5 to 5 mL/min. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear.^{17,18}

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Time is better spent administering IV sodium nitrite. Break one amyl nitrite ampule, and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off.^{7,18} Inhalation of amyl nitrite should be discontinued prior to sodium nitrite administration. The health care provider should be extremely careful not to inhale the amyl nitrite to prevent lightheadedness and syncope. Immediately following the completion of the sodium nitrite infusion, 50 mL of 25% solution (12.5 g) sodium thiosulfate should be infused intravenously. The same needle and vein can be used, and the dose of the thiosulfate can be repeated at half the initial dose whenever manifestations of cyanide toxicity.¹⁸

In situations where additional methemoglobin formation would be harmful, as in patients with carbon monoxide poisoning, it may be safer to withhold the nitrite and only administer the IV hydroxocobalamin with or without sodium thiosulfate. Sodium thiosulfate can be administered through a separate IV line following the hydroxocobalamin. The initial dose of hydroxocobalamin in adults is 5 g IV over 15 minutes with a second dose administered if warranted.⁷

Children

Intravenously inject 0.2 mL/kg (6 to 8 mL/m² BSA) or 6 mg/kg of 3% sodium nitrite solution, at a rate of 2.5 to 5 mL/min, not to exceed 10 mL or 300 mg.^{17,18} Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/dL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin or sulphemoglobin.² The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear (Table 126-2).¹⁸

The dose of sodium thiosulfate in children is 1 mL/kg using a 25% solution (250 mg/kg or approximately 30–40 mL/m² of BSA) not to exceed 50 mL (12.5 g) total dose immediately following administration of sodium nitrite.^{17,19} The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear. The same needle and vein can be used.

Amyl nitrite inhalation can be used in children at the same dose and with the same precautions as mentioned above for adults.

In situations where additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire in which other toxic gases may coexist, the nitrite can be withheld and hydroxocobalamin administered with or without sodium thiosulfate. In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose has been employed.⁷

Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

FORMULATION AND ACQUISITION

Sodium nitrite is available in ampules containing 300 mg in 10 mL (3% concentration) water for injection (USP).¹⁸ It contains no additives or preservatives. It is also available in a kit known as Nithiodote, containing one vial of sodium nitrite (300 mg in 10 mL water for injection) with one vial of sodium thiosulfate (12.5 g in 50 mL water for injection), with boric acid or sodium hydroxide added to adjust the pH.¹⁷

SUMMARY

- Sodium nitrite is an effective cyanide antidote when administered in a timely fashion and followed by sodium thiosulfate for a synergistic effect.
- The production of methemoglobin is both therapeutic in cyanide poisoning and potentially life threatening if nitrites are administered to a patient with impaired oxygen carrying capacity from elevated levels of carboxyhemoglobin, sulfhemoglobin, or methemoglobin from any cause.
- In situations where additional methemoglobin formation would be harmful, as in patients with carbon monoxide poisoning, it may be safer to withhold the nitrite and administer IV hydroxocobalamin with or without sodium thiosulfate.

A40 ANTIDOTES IN DEPTH

Sodium Thiosulfate

Mary Ann Howland

INTRODUCTION

Sodium thiosulfate is a safe and effective antidote that detoxifies cyanide by donating a sulfur moiety to form thiocyanate. Thiocyanate is much less toxic than cyanide and is renally eliminated. Sodium thiosulfate works synergistically with nitrites and is probably at least additive to hydroxocobalamin in the detoxification of cyanide. Because sodium thiosulfate does not compromise hemoglobin oxygen saturation, it can be used without nitrites in circumstances where the formation of methemoglobin would be detrimental, as in patients who have elevated levels of carboxyhemoglobin or preexistent methemoglobinemia from smoke inhalation, drug exposure, or congenital dyshemoglobinemias when hydroxocobalamin is unavailable. Based on the mechanism of action of sodium thiosulfate, particularly when used alone, it is unlikely to be as effective as hydroxocobalamin, or work as quickly. A recent study in a swine cyanide model could not show a benefit of sodium thiosulfate as sole therapy or show an added benefit to that offered by hydroxocobalamin.³ Sodium thiosulfate is used prophylactically with nitroprusside to prevent cyanide toxicity. Sodium thiosulfate is also used to treat calcific uremic arteriolopathy (calciophylaxis) theoretically by increasing the solubility of calcium deposits, inducing vasodilation, and acting as a free radical scavenger.^{6,24,28,32}

HISTORY

In 1933, Chen and colleagues⁸ noted that preexposure treatment with intravenous (IV) sodium thiosulfate protected dogs against three minimum lethal doses of sodium cyanide, and even more remarkable were the synergistic effects obtained by combining sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite, which protected the dogs against 10 to 18 minimum lethal doses of cyanide.^{7,8}

PHARMACOLOGY

Chemistry

The chemical formula of sodium thiosulfate is $\text{Na}_2\text{S}_2\text{O}_3$. The molecular weight of sodium thiosulfate is 248 Da. It forms a pentahydrate that is highly water soluble.

Mechanism of Action

The sulfur provided by sodium thiosulfate binds to cyanide with the help of rhodanese (cyanide sulfur transferase) and mercaptopyruvate sulfur transferase.^{8,36,38} Sulfane sulfur (a divalent sulfur bound to one other sulfur) is the only sulfur that reacts with cyanide to produce thiocyanate, which is minimally toxic and renally eliminated. In several animal models, sodium thiosulfate protects against several minimum lethal doses of cyanide.^{16,20} The addition of rhodanese increases the efficacy of sodium thiosulfate, but the use of rhodanese is impractical in the clinical setting.^{20,37} The cationic site on rhodanese is crucial to cleaving the sulfur–sulfur bond of thiosulfate and forming a sulfur–rhodanese complex that readily reacts with cyanide.³⁸

Rhodanese is probably not solely responsible for sulfur–sulfur bond cleavage, as rhodanese is largely a mitochondrial enzyme found in the liver and skeletal muscle, and sodium thiosulfate is a divalent ion that poorly crosses membranes.^{12,20,25,36,38} It is also suggested that both mercaptopyruvate sulfurtransferase and rhodanese are involved in the formation of sulfane sulfur in the liver from sodium thiosulfate, and that serum albumin then carries the sulfane sulfur from the liver to other organs. When cyanide is present, albumin delivers this sulfur to cyanide, forming thiocyanate.^{17,36–38}

Pharmacokinetics and Pharmacodynamics

Animal Studies. Sodium thiosulfate is a large divalent anion. Canine studies suggest that sodium thiosulfate rapidly distributes into the extracellular space and then slowly into the cell, perhaps with a carrier facilitating entry into the mitochondria.^{15,25} When administered prior to cyanide, thiosulfate converted more than 50% of the cyanide to thiocyanate within 3 minutes and increased the endogenous conversion rate more than 30 times.³⁵ A canine model employing continuous intravenous (IV) infusion of cyanide to induce a respiratory arrest, demonstrated that the IV administration of 500 mg/kg of sodium thiosulfate decreased the serum cyanide concentration and restored respiration within 3 minutes.¹⁰ Thiosulfate is filtered and secreted in the kidney. At low serum concentrations, thiosulfate is largely reabsorbed, whereas at high serum concentrations filtration and secretion predominate.^{14,25}

Human Studies. A volunteer study examined the pharmacokinetics of sodium thiosulfate and the fate of thiosulfate.^{16,25} After injection of 150 mg/kg, the volume of distribution (Vd) was 0.15 L/kg, the distribution half-life was 23 minutes, and the elimination half-life was 3 hours. The peak serum thiosulfate concentration rose 100 fold. Approximately 50% of the drug was eliminated in 18 hours, most of that within the first 3 hours. Baseline thiosulfate concentrations were higher in starved patients and children, presumably because of their higher protein metabolism to thiosulfate.¹⁶ Normally, the kidney actively reabsorbs thiosulfate, but this study found that with exogenous administration, thiosulfate clearance equaled creatinine clearance.¹⁶

The study of thiosulfate as a cisplatin neutralizer demonstrated a half-life of 80 minutes, and that renal clearance accounted for only 30% of the total clearance.³¹ Oral sodium thiosulfate is poorly absorbed and acts as a laxative.²⁵

A pharmacokinetic study was conducted in healthy volunteers as well as hemodialysis (HD) patients both on and off of HD.¹³ Eight grams of sodium thiosulfate was diluted in 50 mL of 0.9% NaCl and infused over 8 minutes. The use of a population pharmacokinetic model revealed a small Vd (0.226 L/kg), a nonrenal clearance similar to the renal clearance accounting for about 50% of the elimination in both healthy volunteers and HD patients. Total body clearance in the HD patients undergoing HD was double that of the same patients not receiving HD. A one compartment distribution model was assumed due to the absence of rebound concentrations after HD ended. Oral bioavailability was only about 8% and was calculated after 5 g of the IV solution was diluted in 100 mL of water and ingested rapidly.

ROLE IN CYANIDE TOXICITY

In 1952, 16 cyanide-poisoned patients survived following the administration of nitrites and sodium thiosulfate.⁷ Even patients who were unconscious or apneic survived following expeditious cardiopulmonary resuscitation and antidotal therapy.⁷ A more recent study in swine evaluated the effect of hydroxocobalamin with sodium thiosulfate versus sodium nitrite and sodium thiosulfate in a model utilizing a continuous infusion of cyanide. There was no difference between the groups with a metabolic acidosis with an elevated lactate concentration at times 20 and 40 minutes or in cardiac output and pulse rate at 40 minutes, or in mortality. The mean arterial pressure was higher in the hydroxocobalamin with sodium thiosulfate group, beginning at 5 minutes and lasting for the entire 40 minute monitoring period.⁴ A second study in swine done by the same group could not show a benefit to sodium thiosulfate as sole therapy or show an added benefit to hydroxocobalamin in a model following intravenous cyanide exposure.³ All 12 swine in the sodium thiosulfate group died compared to only 1/12 in the hydroxocobalamin group.

Case reports attest to the ability of sodium nitrite and sodium thiosulfate to reverse the effects of cyanide following timely administration.^{9,23,25}

In the few reported cases of cyanide ingestion treated solely with sodium thiosulfate, all patients had favorable outcomes.²⁵ However, prior to sodium thiosulfate administration, we advocate the use of sodium nitrite, or preferably hydroxocobalamin. As noted, nitrites would be relatively contraindicated for patients who have elevated carboxyhemoglobin or methemoglobin concentrations from smoke inhalation.

ROLE IN NITROPRUSSIDE-INDUCED CYANIDE TOXICITY

Canine experiments reveal that when the nitroprusside infusion rate is greater than 0.5 mg/kg/h, cyanide concentrations in the blood begin to rise. Coadministration of sodium thiosulfate with sodium nitroprusside (which contains five cyanide ions) in a 5:1 molar ratio prevents the rise in cyanide concentration.²⁵ The usual dosage of sodium nitroprusside is 3 µg/kg/min (range 0.25–10 µg/kg/min).²¹ Each mole of nitroprusside has a molecular weight of 298 Da, including the sodium dehydrate. A 70 kg person administered 3 µg/kg/min would receive 12.6 mg/h (0.042 mmol/h) of nitroprusside. This would require 52.4 mg (0.211 mmol) of sodium thiosulfate per hour to detoxify the five cyanide ions liberated from nitroprusside. Prolonged infusion or doses in excess of the detoxifying capability of the body may lead to thiocyanate or cyanide toxicity. Some authors recommend adding 0.5 g sodium thiosulfate to each 50 mg of nitroprusside.²² Although this

dose of sodium thiosulfate usually is sufficient to prevent cyanide toxicity from nitroprusside, thiocyanate may accumulate, especially in patients with renal insufficiency. Although thiocyanate is relatively nontoxic compared to cyanide, it may produce dose-dependent tinnitus, miosis, hyperreflexia, and hypothyroidism, especially at serum concentrations greater than 60 µg/mL.²¹ Thiocyanate is hemodialyzable. Nitroprusside-induced cyanide toxicity should be treated by stopping the nitroprusside and administering standard doses of hydroxocobalamin with or without sodium thiosulfate.

ROLE IN CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Sodium thiosulfate decreases calcification of the medial layer of arteries leading to subcutaneous nodules that typically progress to necrotic skin ulcers as a manifestation of this rare vascular disease associated with chronic kidney failure patients.^{1,2,6,24} The dose of sodium thiosulfate is usually 5 to 25 g IV in adults during or after hemodialysis.^{24,27,32} Thiosulfate may increase the water solubility of calcium leading to enhanced excretion of calcium thiosulfate, induce vasodilation, and act as a free radical scavenger.^{27,28,32} In a uremic rat model, sodium thiosulfate was able to prevent vascular calcifications but also induced a metabolic acidosis and reduced bone strength.²⁹ A patient being treated for calcific uremic arteriolopathy developed a severe anion gap metabolic acidosis following each repeated dose of sodium thiosulfate.³⁰

ADVERSE EFFECTS AND SAFETY ISSUES

The toxicity of sodium thiosulfate is low. The LD₅₀ for animals is approximately 3 to 4 g/kg, with death attributed to metabolic acidosis, elevated sodium concentration, and decreased blood pressure and PO₂.²⁰ Sodium thiosulfate is hyperosmolar, delivering a significant sodium load resulting in an osmotic diuretic effect.²⁵ Administering the infusion over 10 to 30 minutes limits some of these adverse effects.²⁵ Adverse effects associated with therapeutic doses include hypotension, nausea, and vomiting.

PREGNANCY AND LACTATION

Sodium thiosulfate is FDA pregnancy Category C. No reports of congenital anomalies in infants born to women exposed to sodium thiosulfate during pregnancy are described.²⁶ Teratogenic effects were not observed in hamster offspring treated with doses of sodium thiosulfate comparable to those that would be used for cyanide toxicity. Sodium thiosulfate should be used in pregnant woman when the potential benefit clearly outweighs any potential risk. It is not known whether sodium thiosulfate is excreted in breast milk.

DOSING AND ADMINISTRATION

Cyanide Toxicity

Adults. In a patient with presumed cyanide poisoning, the adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) administered intravenously either as a bolus injection or infused over 10 to 30 minutes, depending on the severity of the exposure.²⁶ The dose of sodium thiosulfate can be repeated at half the initial dose if manifestations of cyanide toxicity reappear.²⁶

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 300 mg of sodium nitrite (10 mL of 3% solution) at a rate of 2.5 to 5 mL/min prior to administration of sodium thiosulfate. The same needle and injection site can be used. The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear.^{26,33}

Amyl nitrite can be used prior to IV administration of sodium nitrite, but only as a temporizing measure until IV sodium nitrite can be administered. Time is better spent administering IV sodium nitrite.¹⁸ Break one amyl nitrite ampule, and hold it in front of the patient's mouth for 15 seconds on and 15 seconds off. Inhalation of amyl nitrite should be discontinued prior to administration of sodium nitrite. The health care provider must not inhale the amyl nitrite.

In situations where the additional formation of methemoglobin would be harmful, as in patients in whom carboxyhemoglobin or methemoglobin may be present from smoke inhalation, or dyshemoglobinemias or drug-induced methemoglobinemia, the nitrites can be withheld and hydroxocobalamin administered with or without sodium thiosulfate. The initial dose of hydroxocobalamin in adults is 5 g IV over 15 minutes with a second dose administered if warranted.¹¹ Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

Children. The dose of sodium thiosulfate in children is 1 mL/kg using a 25% solution (250 mg/kg or approximately 30–

40 mL/m² of BSA) not to exceed 50 mL (12.5 g) total dose immediately following administration of sodium nitrite.^{26,34} The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear.

In situations where the formation of methemoglobin by a nitrite would not be harmful, intravenously inject 3% sodium nitrite solution at 0.2 mL/kg (6–8 mL/m² or 6 mg/kg) at a rate of 2.5 to 5 mL/min not to exceed 10 mL or 300 mg, prior to administration of sodium thiosulfate. The same needle and vein can be used. Based on an in vitro calculation, this dose would be safe for a child with a hemoglobin of 7 g/dL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as carboxyhemoglobin, methemoglobin, or sulfhemoglobinemia.⁵ The dose of sodium nitrite can be repeated at half the initial dose if manifestations of cyanide toxicity reappear or at 2 hours after the first dose as prophylaxis.

Amyl nitrite inhalation can be used in children at the same dose and with the same precautions as mentioned above for adults.

In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose has been employed.¹¹ Sodium thiosulfate is often used following hydroxocobalamin to provide an added benefit, although the extent of this added benefit has been questioned.³ Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line since a physical incompatibility occurs, inactivating the hydroxocobalamin.

FORMULATION AND ACQUISITION

Sodium thiosulfate is available in 50-mL vials containing 12.5 g in water for injection (USP), with boric acid or sodium hydroxide added to adjust the pH.³⁴ It is available in a kit known as Nithiodote, containing one vial of sodium nitrite (300 mg in 10 mL water for injection) with one vial of sodium thiosulfate (12.5 g in 50 mL water for injection), with boric acid or sodium hydroxide added to adjust the pH.²⁶

SUMMARY

- Sodium thiosulfate detoxifies cyanide by forming thiocyanate.
- The action of sodium thiosulfate is slower in onset than hydroxocobalamin or the nitrites.
- Thiocyanate is significantly less toxic than cyanide and is renally eliminated.
- Prophylactic administration of sodium thiosulfate along with sodium nitroprusside reduces cyanide toxicity by converting liberated cyanide to thiocyanate.
- Sodium thiosulfate is synergistic with nitrites.
- Sodium thiosulfate may be used following hydroxocobalamin, but animal data do not demonstrate an added benefit.

A41 ANTIDOTES IN DEPTH

Hydroxocobalamin

Mary Ann Howland

INTRODUCTION

Cyanocobalamin, vitamin B₁₂, is formed when hydroxocobalamin combines with cyanide, quickly dropping cyanide concentrations and improving hemodynamics. Nitrites and sodium thiosulfate have traditionally been used to treat patients with cyanide toxicity. Nitrites have the disadvantage of producing methemoglobin, which is dangerous in a patient with coexistent elevated carboxyhemoglobin concentrations, such as would be found in fire victims suspected of having cyanide toxicity. Based on the mechanism of action of sodium thiosulfate, particularly when used alone, it is unlikely to be as effective as hydroxocobalamin, or work as quickly. A recent study in swine did not show a benefit to sodium thiosulfate as sole therapy or show an added benefit to hydroxocobalamin in a model of intravenous cyanide toxicity.⁷

HISTORY

The antidotal actions of cobalt as a chelator of cyanide were recognized as early as 1894.^{15,47} Hydroxocobalamin has been used as a cyanide antidote in France for many years, first as a sole agent and then in combination with sodium thiosulfate.²⁵ Hydroxocobalamin was finally approved by the Food and Drug Administration (FDA) in December 2006 and is available under the trade name Cyanokit.^{14,16}

In experimental models, hydroxocobalamin was successful in protecting against several minimum lethal doses of cyanide when an equimolar ratio of hydroxocobalamin to cyanide was used.^{1,10,36,43}

PHARMACOLOGY

Chemistry

The molecule is porphyrinlike in structure and has a cobalt ion at its core. The only difference between cyanocobalamin (vitamin B₁₂) and hydroxocobalamin (vitamin B_{12a}) is the replacement of the CN group with an OH group at the active site in the latter.^{31,38}

Mechanism of Action

The cobalt ion in hydroxocobalamin combines with cyanide to form the nontoxic cyanocobalamin.^{35,36} One mole of hydroxocobalamin binds 1 mole of CN. Given the molecular weights of each, 52 g of hydroxocobalamin are needed to bind 1 g of cyanide.²⁵ An ex vivo study using human skin fibroblasts demonstrated that hydroxocobalamin penetrates intracellularly to form cyanocobalamin.² In the setting of cyanide poisoning, hydroxocobalamin removes cyanide from the mitochondrial electron transport chain, allowing oxidative metabolism to proceed. Hydroxocobalamin also binds nitric oxide, a vasodilator, causing vasoconstriction both in the presence and in the absence of cyanide. This same property potentially contributes to its beneficial effects by increasing systolic and diastolic blood pressure and improving the hemodynamic status of cyanide poisoned patients.^{10,21} Other cobalt chelators, such as dicobalt ethylenediaminetetraacetic acid (EDTA), have been used both experimentally and clinically in other countries, but their therapeutic index is narrow, especially in the absence of cyanide. Additionally, idiosyncratic adverse effects make these compounds less advantageous.^{35,47} In France, hydroxocobalamin is used with sodium thiosulfate as it is thought to have an additive effect in the treatment of cyanide.^{41,44}

Pharmacokinetics and Pharmacodynamics

Under an FDA Investigational New Drug permit, the first pharmacokinetic study of intravenous (IV) hydroxocobalamin was performed in the United States and published in 1993.^{16,17} Adult volunteers who were heavy smokers were given 5 g hydroxocobalamin (5%) intravenously. The first four patients received the dose undiluted over 20 minutes.¹⁷ Then they received 12.5 g (50 mL of 25% solution) of sodium thiosulfate intravenously infused over 20 minutes. The next 11 patients received the same dose of hydroxocobalamin but diluted with 100 mL water for injection (USP) and infused over 30 minutes. The serum and urine sampling of hydroxocobalamin differed in the two patient groups, yielding somewhat different half-lives (4 vs. 1.27 hours). The α distribution half-life was 0.52 hours in the group 1 patients. Peak hydroxocobalamin concentrations averaged 813 $\mu\text{g/mL}$ (604 $\mu\text{mol/L}$), and volume of distribution (Vd) averaged 0.38 L/kg. A mean of 62% of the dose was recovered in the urine in 24 hours. Whole-blood cyanide concentrations significantly decreased in all subjects following hydroxocobalamin. A problem with this study was the short collection time for serum hydroxocobalamin concentrations of only 6 hours, making the pharmacokinetic analysis imprecise.^{27,28}

A pharmacokinetic study in France²⁵ was conducted in adult victims of smoke inhalation given hydroxocobalamin, 5 g (5%) by IV infusion over 30 minutes, starting within 30 minutes of patient removal from the fire.^{27,28} The α distribution half-life of hydroxocobalamin was 1.86 hours, elimination half-life was 26.2 hours based on sampling up to 6 days, and the Vd was 0.45 L/kg. The peak serum cyanocobalamin concentration was 287 $\mu\text{g/mL}$ (212 $\mu\text{mol/L}$). In the one patient who was subsequently determined not exposed to cyanide, the hydroxocobalamin elimination half-life was 13.6 hours and Vd was 0.23 L/kg. Renal clearance of hydroxocobalamin was 37% in the cyanide-exposed patients compared with 62% in the unexposed patient.

In another study in France in which 12 fire victims were suspected of having cyanide poisoning, the patients received IV hydroxocobalamin 5 g in 100 mL sterile water (USP) over 30 minutes.³⁰ Pretreatment and posttreatment cyanide concentrations and cyanocobalamin concentrations were analyzed. In patients with cyanide concentrations less than 1.04 $\mu\text{g/mL}$ (< 40 $\mu\text{mol/L}$), a linear relationship existed between the blood cyanide concentration and the formation of cyanocobalamin. In the three patients with blood cyanide concentration greater than 1.04 $\mu\text{g/mL}$ (> 40 $\mu\text{mol/L}$), the formation of cyanocobalamin reached a plateau, implying that all the hydroxocobalamin was consumed. When the patient with a blood cyanide concentration greater than 1.04 $\mu\text{g/mL}$ (> 40 $\mu\text{mol/L}$) received a second 5 g dose of hydroxocobalamin, the cyanocobalamin concentration subsequently rose.^{3,30}

The protein binding and tissue distribution of cyanide, hydroxocobalamin, and cyanocobalamin likely are different.²⁹ In addition, hydroxocobalamin probably causes redistribution of cyanide from the intracellular to the intravascular space.²⁹

ROLE IN CYANIDE TOXICITY

Animals

The ability of hydroxocobalamin to bind cyanide and produce beneficial effects on mortality and hemodynamics has been

demonstrated in many animal species, including rabbits, swine, dogs, and baboons.²⁶ A recent study in swine evaluated the effect of hydroxocobalamin plus sodium thiosulfate versus sodium nitrite and sodium thiosulfate in a model utilizing a continuous infusion of cyanide. There was no difference between the groups with regard to metabolic acidosis with an elevated lactate concentration at times 20 and 40 minutes, cardiac output and pulse rate at 40 minutes, or mortality. The mean arterial pressure was higher in the hydroxocobalamin plus sodium thiosulfate group, beginning at 5 minutes and lasting for the entire 40 minute monitoring period.⁸ A second cyanide study in swine done by the same group could not show a benefit to sodium thiosulfate as sole therapy or show an added benefit of sodium thiosulfate to hydroxocobalamin.⁷

Humans

Many case reports and studies in France document the efficacy of hydroxocobalamin combined with sodium thiosulfate for treatment of cyanide toxicity.^{6,11,20,24} An observational case series reviewed 69 adult smoke inhalation victims suspected of cyanide poisoning who were treated either at the scene of the fire or in the intensive care unit (ICU).¹⁰ They received a median dose of 5 g of hydroxocobalamin, up to a maximum of 15 g, infused as a 5% solution in sterile water for injection over 15 to 30 minutes. Cardiopulmonary arrest occurred in 15 patients, with a mean blood cyanide concentration of 123 $\mu\text{mol/L}$ ($100 \mu\text{mol/L} = 2.7 \mu\text{g/mL}$, which is a fatal concentration if untreated) and a mean carboxyhemoglobin of 30%. Two of these patients survived with normal neurologic function. Of 42 patients with confirmed cyanide concentrations greater than 39 $\mu\text{mol/L}$ ($1 \mu\text{g/mL}$, which is potentially fatal), 28 (67%) survived. The contribution to toxicity of carboxyhemoglobin is difficult to determine in this study. Of the 69 patients in this study, 57 also received hyperbaric oxygen, complicating the interpretation of the outcome.¹⁰

An 8 year retrospective analysis of the use of hydroxocobalamin in the prehospital setting concluded that the risk-to-benefit ratio favors its use in smoke inhalation victims suspected of cyanide poisoning.¹⁸ Of 72 patients in whom survival status could be determined, 30 (42%) survived. Cyanide blood concentrations were not measured in these patients. Although 21 of the 38 patients found in cardiac arrest had hemodynamic improvement, survival was dismal with only two patients ultimately surviving. The neurologic function of those two patients was not described.

Hydroxocobalamin also prevented the rise in cyanide concentration following nitroprusside infusion compared with patients who only received nitroprusside.¹² When nitroprusside is administered, the use of concomitant hydroxocobalamin prevents cyanide accumulation and toxicity in both animal models and in humans.^{11,12,48} Sodium thiosulfate also prevents nitroprusside induced cyanide toxicity (Antidotes in Depth: A40). There are currently no studies comparing the nitrite plus sodium thiosulfate regimen with hydroxocobalamin in patients with cyanide poisoning.⁴¹ There are no studies comparing hydroxocobalamin with or without sodium thiosulfate to sodium thiosulfate alone in smoke inhalation victims presumed to be cyanide toxic.

The kidneys, heart, and liver of a patient who was declared brain dead after third degree burns and smoke inhalation following a fire, were successfully transplanted into four patients.¹⁹ The victim received 10 g of hydroxocobalamin. Whole-blood cyanide concentrations were later confirmed to be significantly elevated.

ADVERSE EFFECTS AND SAFETY ISSUES

Hydroxocobalamin has a wide therapeutic index.^{10,18,46} Large doses have been administered to animals with no adverse effects.^{35,40,42} The LD_{50} (median lethal dose in 50% of test subjects) in mice is 2 g/kg.

Red discoloration of mucous membranes, serum, and urine may occur and last from 12 hours to many days after therapy.^{10,14,18} Patients should be warned to avoid direct sun exposure while their skin remains red for fear of a photosensitivity reaction.¹⁴ Allergic reactions including anaphylaxis and angioedema are reported, but serious allergic reactions are rare.^{5,6,11,38} Prior chronic exposure to hydroxocobalamin or cyanocobalamin for treatment of vitamin B₁₂ deficiency is associated rarely with development of anaphylaxis.²⁵ A study in 102 healthy volunteers demonstrated that chromaturia is universal, and as the dose increases from 2.5 to 10 g, the incidence of erythema, rash (predominantly acneiform), headache, injection site reaction, nausea, pruritus, chest discomfort, and dysphagia increases.⁴⁶ The dermatologic manifestations are quite variable, both rapid and delayed onset with protracted courses may occur. Of 102 volunteers randomized to receive hydroxocobalamin, 24 experienced a clinically significant rise in diastolic blood pressures, up to 124 mm Hg. However, only three of them also had clinically significant elevations in systolic blood pressure. These elevations in blood pressure resolved within 4 hours of the end of the infusion. Urinary oxalate crystals were reported in patients receiving hydroxocobalamin whether or not the patient is exposed to cyanide.¹⁴

Colorimetric assays are most likely to be adversely affected because both hydroxocobalamin and cyanocobalamin have an intensely red color. Many clinical chemistry laboratory tests can be artificially increased, decreased, or unpredictable.^{9,14} Hematology tests including hemoglobin, MCH, MCHC, and basophils are artificially increased.¹⁴ Coagulation tests are unpredictable. Urinalysis tests are usually artificially increased, but pH can also be artificially low

with low doses of hydroxocobalamin.¹⁴ An in vitro study found statistically significant alterations in serum concentrations of aspartate aminotransferase (AST), total bilirubin, creatinine, magnesium, and iron after hydroxocobalamin administration.¹³ Although an in vitro study demonstrated a considerable false increase in carboxyhemoglobin concentrations following hydroxocobalamin administration when measured by cooximetry, other authors suggest that the interference is minimal and results in slight overestimates depending on the instrument and the concentration of hydroxocobalamin.^{4,22,32} Inconsequential increases of 1% to 5.7% in the carboxyhemoglobin level were reported in another study.²² However, more worrisome is the report of two instances where the carboxyhemoglobin levels were falsely low by a factor of 4 to 14 times.³⁴

Because of the inaccuracies in laboratory determinations, blood should be drawn before the administration of hydroxocobalamin whenever possible. This is particularly important in fire victims when carboxyhemoglobin concentrations may be necessary for management decisions.

PREGNANCY AND LACTATION

Hydroxocobalamin is FDA pregnancy category C. Animal studies are insufficient and there are no controlled trials in pregnant women. Hydroxocobalamin should be used in pregnant women when the potential benefit outweighs the potential risk to the fetus. A pregnant woman in her fourth week of gestation was inadvertently administered 5 g of hydroxocobalamin during a volunteer study. She went on to deliver a normal healthy baby at term.¹⁴

DOSING AND ADMINISTRATION

Cyanide Toxicity

The initial dose of hydroxocobalamin in adults is 5 g. Each vial is reconstituted with 200 mL of 0.9% sodium chloride and administered intravenously over 15 minutes. If 0.9% sodium chloride is unavailable, lactated ringers solution or D₅W may be used. Each vial should be inverted or rocked (not shaken) for 60 seconds prior to administration. The reconstituted solution should be dark red and free of particulate matter and should be used within 6 hours of reconstitution.¹⁴ A second dose of 5 g can be repeated as clinically necessary and infused over 15 minutes to 2 hours depending on patient status.¹⁴

In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose is recommended.¹⁴

Sodium thiosulfate can be administered in addition to hydroxocobalamin, but the administration of the hydroxocobalamin should take precedence. The sodium thiosulfate is expected to be additive and has been used extensively in conjunction with hydroxocobalamin.^{23,24,33} Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate simultaneously through the same IV line since this may inactivate the hydroxocobalamin.²⁹ The adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) and should be administered intravenously as either a bolus injection or infused over 10 to 30 minutes, depending on the severity of the situation. The dose of sodium thiosulfate in children is 1 mL/kg using a 25% solution (250 mg/kg or approximately 30–40 mL/m² of BSA) not to exceed 50 mL (12.5 g) total dose. The dose can be repeated at half the initial dose if manifestations of cyanide toxicity reappear.^{39,45}

Nitroprusside Induced Cyanide Toxicity

Nitroprusside induced cyanide toxicity should be treated like cyanide toxicity from any other cause: stop the nitroprusside dosage and administer hydroxocobalamin with or without sodium thiosulfate according to the doses and precautions listed. The dose of hydroxocobalamin to prevent cyanide toxicity from the IV infusion of nitroprusside is not precisely known, but a dose of hydroxocobalamin of 25 mg/h in one study was sufficient to decrease the red cell and serum cyanide concentrations and to prevent the development of a metabolic acidosis while the nitroprusside continued to be administered.⁴⁸ These authors recommend possibly continuing the hydroxocobalamin for 10 hours after the discontinuation of the nitroprusside. Hydroxocobalamin could also be used as rescue therapy in the typical dosage, as could sodium thiosulfate (Antidotes in Depth: A40).

FORMULATION AND ACQUISITION

Each Cyanokit contains one 250 mL glass vial containing 5 g of lyophilized dark red, hydroxocobalamin crystalline powder for injection.¹⁴ The kit also contains one sterile transfer spike, one sterile IV infusion set, one quick reference guide, and one package insert, but no diluent.

SUMMARY

- Hydroxocobalamin is effective for cyanide toxicity generated from all routes of exposure. Intravenous hydroxocobalamin is safe in the setting of a fire when carboxyhemoglobin is also expected to be present.
- Hydroxocobalamin affects all laboratory tests that are colorimetric, producing falsely elevated or lowered results. Of particular importance may be the significantly falsely diminished assay for carboxyhemoglobin.
- Hydroxocobalamin causes a red discoloration of the skin and mucous membranes that may last hours to days.

127 METHEMOGLOBIN INDUCERS

Dennis P. Price

HISTORY AND EPIDEMIOLOGY

Methemoglobinemia is a disorder of the red blood cell. Exposure to various xenobiotics can adversely affect the red cell membrane, intracellular metabolism, and, as is the case with methemoglobinemia, interfere with hemoglobin function. Methemoglobin occurs when the iron atom in hemoglobin loses one electron to an oxidant, and the ferrous (Fe^{2+}) or oxidized state of iron is transformed into the ferric (Fe^{3+}) state. Although methemoglobin is always present at low concentrations in the body, methemoglobinemia is defined herein as an abnormal elevation of the methemoglobin level above 1%. The ubiquity of oxidants, both in the environment and in the hospital, has increased the number of cases of reported methemoglobinemia.

Methemoglobin was first described by Felix Hoppe-Seyler in 1864.³⁵ Subsequently, in 1891, a case of transient drug induced methemoglobinemia was described.⁷³ In the late 1930s, methemoglobinemia was recognized as a predictable adverse effect of sulfanilamide use, and methylene blue was recommended for treatment of the ensuing cyanosis.^{46,108} Some authors even recommended concurrent use of methylene blue when sulfanilamides were used.¹⁰⁸ Methylene blue was used prophylactically during general surgery to treat an individual with congenital methemoglobinemia.⁷ In 1948, an enzyme identified as coenzyme 1 was reported in six patients in two families who had idiopathic methemoglobinemia. The defect in coenzyme 1 (NADH methemoglobin reductase) caused cyanosis in the absence of cardiopulmonary disease and responded to ascorbic acid.³⁷

Methemoglobinemia may be hereditary or acquired. The hereditary types are rare, with only several hundred cases reported.^{47,103} Although the frequency with which xenobiotic-induced methemoglobinemia occurs is unknown, the American Association of Poison Control Centers' annual data over the past 5 years has shown approximately 100 yearly uses of methylene blue as an antidote. These data substantially underestimate the incidence of this poisoning because poison centers are not notified in most cases (Chap. 136).

Methemoglobinemia is relatively common and generally produces no clinical findings. Cooximetry data collected at two teaching hospitals noted a significant number of elevated methemoglobin levels.⁴ Of a total of 5248 cooximetry tests over 28 months on 1267 patients, 660 tests revealed methemoglobin levels above 1.5% in 414 patients (some patients had more than one test). Thus, 12.5% of all tests and 19.1% of all patients who had cooximetry performed had an abnormal methemoglobin level. A total of 138 patients with peak methemoglobin levels greater than 2% were identified. The mean peak methemoglobin level was 8.4% (range, 2.1%–60.1%), and the ages of the patients ranged from 4 days to 86 years.⁴

Benzocaine spray accounted for the most seriously poisoned patients ($n = 5$), with a mean peak methemoglobin level of 43.8% (range, 19.1%–60.1%).⁴ Dapsone accounted for the largest number of cases ($n = 58$), with a mean peak of 7.6% (range, 2.1%–34.1%). Of those patients who had elevated methemoglobin levels, 8% had symptomatic methemoglobinemia, approximately one-third received methylene blue. One fatality and three near-fatalities were directly attributed to methemoglobinemia. These data likely represent an underestimation of the true number of cases of methemoglobinemia at these institutions because cooximetry was performed only on physician orders for suspected dysmethemoglobinemia, and 25% of cases with levels above 2% were found incidentally when cooximetry was performed in the catheterization laboratory to provide data on oxyhemoglobin and deoxyhemoglobin. In addition, not all patients taking dapsone were tested.⁴ Extrapolating these data throughout the country would suggest underreporting and substantial underrecognition of this entity with its potential danger.

Another study screened a small sample of infants younger than 3 months of age who presented to the emergency department with dehydration due to diarrhea. A small number of patients had elevated levels of methemoglobin.³¹ Furthermore, the incidence of induced methemoglobinemia in the workplace is poorly documented. A number of reports document several hundred such cases of methemoglobinemia and several more workplace exposures.^{15,62,88} Underreporting and underrecognition occur because of the limited symptoms associated with low levels of methemoglobin in most cases. Acute pesticide poisoning leading to methemoglobinemia is common in many parts of the world. In Sri Lanka, a large, multicenter study followed 431 patients with intentional propanil ingestions and found a 10.7% mortality rate in those with methemoglobinemia.⁹² Copper sulfate is another commonly found substance used industrially and as a pesticide that causes

both methemoglobinemia and hemolysis.^{34,76,101}

HEMOGLOBIN PHYSIOLOGY

Hemoglobin consists of four polypeptide chains noncovalently attracted to each other. Each of these subunits carries one heme molecule deeply within the structure. The polypeptide chain protects the iron moiety of the heme molecule from inappropriate oxidation (Fig. 127–1).

FIGURE 127–1. Hemoglobin molecule symbolically represented with its heme center surrounded by the globin portion of the molecule. his = histidine.

The iron is held in position by six coordination bonds. Four of these bonds are between iron and the nitrogen atoms of the protoporphyrin ring with the fifth and sixth bond sites lying above and below the protoporphyrin plane. The fifth site is occupied by histidine of the polypeptide chain. A variety of hemoglobin mutations are attributable to changes in the amino acid sequence of the polypeptide chain, as with hemoglobin M diseases. This influences this protective “pocket,” allowing easier iron oxidation (Fig. 127–2), or hemoglobin autooxidation. The sixth coordination site is where most of the activity within hemoglobin occurs. Oxygen transport occurs here, and this site is involved with the formation of methemoglobin or carboxyhemoglobin (Fig. 127–3). It is at this site that an electron is lost to oxidant xenobiotics, transforming iron from its ferrous (Fe^{2+}) to its ferric (Fe^{3+}) state.

FIGURE 127–2. Hemoglobin M occurs when histidine is replaced by tyrosin in the amino acid sequence of the polypeptide chain. Hemoglobin M is more easily autooxidized (as shown) to methemoglobin.

FIGURE 127–4. Role of glycolysis in the Embden-Meyerhof pathway and the role of methylene blue in the reduction of methemoglobin using NADPH generated by the hexose monophosphate shunt. Hb (Fe^{3+}) is methemoglobin.

Oxidized iron can be reduced nonenzymatically using either ascorbic acid or reduced glutathione as electron donors, but this method is slow and quantitatively less important under normal circumstances.

Within the red cell is another enzyme system for reducing oxidized iron that is dependent on the NADPH generated in the hexose monophosphate shunt pathway (Fig. 127–4). Although it is generally accepted that this NADPH-dependent system reduces only a small percentage of methemoglobin under normal circumstances, it may play a more prominent role in maintaining oxidant balance in the cell.⁶¹ Patients with an isolated deficiency of NADPH methemoglobin reductase do not exhibit methemoglobinemia under normal circumstances,⁹⁶ perhaps because of the prominence of other cellular protective mechanisms.

However, when the NADPH methemoglobin reductase system is provided with an exogenous electron carrier, such as methylene blue, this system is accelerated and may assist in the reduction of oxidized hemoglobin (Antidotes in Depth: A42).

XENOBIOTIC INDUCED METHEMOGLOBINEMIA

Nitrates and nitrites are powerful oxidizing agents that are two of the most common methemoglobin-forming compounds. Sources of nitrates and nitrites include well water, food, industrial compounds, and pharmaceuticals. Nitrogen-based fertilizers and nitrogenous waste from animal and human sources may contaminate shallow rural wells. Community-based water serves the majority of Americans; however, there are 37 million private wells in the United States. These wells are not tested regularly and may be more shallow than necessary to prevent contamination from fertilizers.^{5,20} The contamination of drinking water occurs mainly with nitrates because nitrites are easily oxidized to the highly soluble nitrates in the environment. Furthermore, foods such as cauliflower, carrots, spinach, and broccoli have high nitrate content, as do preservatives in meat products such as hot dogs and sausage.⁶

The reactions of nitrates that occur both in vivo and in vitro are complex and poorly understood. Ingested nitrates are reduced to nitrites by bacteria in the gastrointestinal (GI) tract (especially in infants) and then can be absorbed, ultimately leading to methemoglobin production. However, this conversion is not essential because nitrates themselves can oxidize hemoglobin.^{32,45,102} Some question whether well water consumption alone can cause serious methemoglobinemia in the absence of comorbid disease.²⁸

In the past, nitrate-contaminated well water was associated with infant fatalities because of methemoglobinemia.^{63,71} A number of reports from the midwestern United States demonstrated the problems of poorly constructed shallow wells that permit contamination by surface waters containing chemicals, pesticides, fertilizers, and microorganisms.⁷⁴ In several South Dakota studies, 20% to 50% of wells contained both coliform bacteria and water that exceeded the Environmental Protection Agency standards for permissible quantities of nitrogen as nitrates (10 ppm or 10 mg/L).⁵⁴ In New York, 419 wells from rural farms demonstrated elevated concentrations of nitrogen compounds, and 15.7% were found to have well water nitrate concentrations higher than 10 mg/L.³⁶ In Texas, wells that were studied longitudinally have shown increasing nitrate contamination.²⁰ Governmental programs, such as the Private Well Initiative, are aiming to improve drinking water quality throughout the country.⁵

Nitroglycerin (glyceryl trinitrate) and organic nitrates are more effectively absorbed through mucous membranes and intact skin than from the GI tract. Their onset of action is more rapid, and the total effect is much greater, when mucous membrane or cutaneous absorption occurs.^{22,50,85} Aromatic amino and nitro compounds indirectly produce methemoglobin.⁵⁷ These xenobiotics do not form methemoglobin in vitro; therefore, they are assumed to do so by in vivo metabolic chemical conversion to some active intermediates.^{15,59}

Elevated methemoglobin and carboxyhemoglobin levels are found in victims of fires and automobile exhaust fume poisoning.^{12,50,56,67} Heat-induced hemoglobin denaturation in burn patients and the inhalation of oxides of nitrogen from combustion are suggested to be causative factors for methemoglobin formation.

Topical anesthetics are widely used to facilitate multiple procedures and are implicated in the most serious of toxic methemoglobin cases.^{1,43} These xenobiotics continue to be a problem despite numerous case studies and recommendations by authors and manufacturers about safe use standards.^{23,40,53} Cetacaine spray (14% benzocaine, 2% tetracaine, 2% butylaminobenzoate) and 20% benzocaine sprays commonly produce methemoglobinemia. The dosing recommendations are difficult to comprehend (eg, 0.5-second spray repeat once) and are often ignored. One study showed that the dose is dependent on the residual volume in the canister and the physical orientation of the canister as the spray is being applied.⁶⁰

A review of 52 months of data from the US Food and Drug Administration (FDA) Adverse Event Reporting System demonstrated 132 cases of benzocaine-induced methemoglobinemia. Benzocaine spray was implicated in 107 severe adverse events and two deaths. In 123 cases, the product was a spray. In 69 cases in which the dose was specified, 37

patients received a single spray.⁷⁵

This FDA effort is exclusively based on self-reporting and probably greatly underestimates the extent of the problem.⁴¹ The FDA itself has estimated that approximately 10% of serious events are reported and that some studies show 1% or less serious event reporting.⁷⁵

In one institution, the incidence of benzocaine-induced methemoglobinemia occurring during transesophageal echocardiograms was determined in 28,478 patients over a 90-month period. The incidence was low at 0.067% (1 case per 1499 patients), with sepsis, anemia, and hospitalization suggested as predisposing factors.⁵⁵ During a 32-month period at another institution, an incidence of 0.115% (5 of 4336) of benzocaine-induced methemoglobinemia was observed.⁸¹ There were no cases of methemoglobinemia in a study of 154 patients receiving lidocaine for bronchoscopy at doses as high as 15 mg/kg. Lidocaine is a much weaker oxidant than benzocaine and is a reasonable substitute in susceptible individuals and has been recommended by some authors.⁵³

Nitric oxide (NO) delivered by inhalation is used to treat persistent pulmonary hypertension of newborns and other cardiopulmonary diseases associated with pulmonary hypertension because it is a potent vasodilator.⁹³ Despite being a potent oxidant, if NO is used in doses of less than 40 ppm, most patients will maintain methemoglobin levels below 4%.^{48,107} Some cases of serious toxicity have occurred because of intentional and unintentional overdoses.

Dapsone is implicated as a cause of methemoglobinemia and is used in patients with AIDS.⁸⁴ Cases of prolonged methemoglobinemia from dapsone ingestion are related to the long half-life of dapsone and the slow conversion to its methemoglobin-forming hydroxylamine metabolites.²⁵ Patients receiving dapsone should be carefully monitored for methemoglobinemia.¹¹⁰ The bladder analgesic phenazopyridine is a commonly reported cause of methemoglobinemia.^{21,30,36,77} For this reason, its use should be limited to short periods of time and at the lowest dose to improve symptoms. This approach is particularly pertinent in the presence of kidney failure. Predispositions for methemoglobinemia are listed in [Tables 127–1 and 127–2](#).

TABLE 127–1. Factors That May Predispose an Individual to Methemoglobinemia

Acidosis ^{84,96}	Diarrhea ^{37,77}
Advanced age ⁷²	Hospitalization ^{47,72}
Age < 36 months ^{21,69,95}	Kidney failure ³³
Anemia ⁴⁷	Malnutrition
Concomitant oxidant use ^{3,58,73}	Sepsis ^{47,57,72,74}

TABLE 127–2. Causes of Methemoglobinemia

Hereditary

- Hemoglobin M
- Cytochrome b₅ reductase deficiency (homozygote and heterozygote)

Acquired

- Medications
 - Amyl nitrite
 - Benzocaine
 - Dapsone
 - Lidocaine
 - Nitric oxide
 - Nitroglycerin
 - Nitroprusside
 - Phenazopyridine

Prilocaine

Quinones (chloroquine, primaquine)

Sulfonamides (sulfanilamide, sulfathiazide, sulfapyridine, sulfamethoxazole)

Other Xenobiotics

Aniline dye derivatives (shoe dyes, marking inks)

Chlorobenzene

Fires (heat-induced denaturation)

Organic nitrites (eg, Isobutyl nitrite, butyl nitrite)

Naphthalene

Nitrates (eg, well water)

Nitrites (eg, foods)

Nitrophenol

Nitrogen oxide gases (seen in arc welders)

Silver nitrate

Trinitrotoluene

Pediatric

Reduced NADH methemoglobin reductase activity in infants (< 4 months)

Associated with low birth weight, prematurity, dehydration, acidosis, diarrhea, and hyperchloremia

Underlying illness,^{31,55,65,81,83} the treatment with xenobiotics for these illnesses,^{3,18,59,66,74,82} and the diagnostics and therapeutic modalities^{48,73} in patient care all predispose patients to methemoglobinemia. For many individuals, methemoglobin is not caused by one oxidant stressor, but rather by a series of stressors that makes methemoglobinemia clinically apparent and potentially predictable.

METHEMOGLOBINEMIA AND HEMOLYSIS

The enzyme defect responsible for most instances of oxidant-induced hemolysis is G-6-PD deficiency. Reviews of hemolysis addressed the confusion regarding the relationship between hemolysis and methemoglobinemia.^{10,11,33}

Both hemolysis and methemoglobinemia are caused by oxidant stress, and hemolysis may occur after episodes of methemoglobinemia.^{11,84} Certain protective mechanisms involving NADPH and reduced glutathione nonspecifically reduce the oxidant burden and prevent the development of both disorders. Another source of confusion concerning hemolysis and methemoglobinemia is that reduced glutathione is required to protect against both toxic manifestations. Erythrocytes can withstand hemolytic oxidant damage as long as they can maintain adequate concentrations of reduced glutathione, the principal cellular antioxidant. Glutathione is maintained in its reduced form by using NADPH as its reducing agent. Cells with reduced capacity to produce NADPH (ie, erythrocytes of patients with G-6-PD deficiency or cells with depleted reduced glutathione or NADPH) are thus susceptible to hemolysis. In the presence of methemoglobinemia, reduced glutathione plays a minor role as a reducing agent, but NADPH is necessary for successful antidotal therapy with methylene blue. This codependence on the reducing power of NADPH links the two disorders. Competition for NADPH by oxidized glutathione and exogenously administered methylene blue is postulated to be the cause of methylene blue-induced hemolysis (ie, competitive inhibition of glutathione reduction). Methylene blue itself is an oxidant, but in an assessment of the hemolytic potency of varied drugs, methylene blue in doses of 390 to 780 mg proved to be only a moderate hemolytic agent.⁵⁸ The clinical importance of this phenomenon is uncertain. It may be easier to consider hemolysis and methemoglobin formation as subclasses of disorders of oxidant stress. They should be considered separate clinical entities sharing limited characteristics.

However, oxidative damage to erythrocytes occurs at different locations in the two disorders. Hemolysis occurs when oxidants damage the hemoglobin chain acting directly as electron acceptors or through the formation of hydrogen peroxide or other oxidizing free radicals. This results in oxidants forming irreversible bonds with sulfhydryl group of hemoglobin cause denaturation and precipitation of the globin protein to form Heinz bodies within the erythrocyte (Fig. 127–5). Cells with large numbers of Heinz bodies are removed by the reticuloendothelial system, producing hemolysis. Alternatively, a limited number of oxidants can destroy the erythrocyte membrane directly, causing non-Heinz body hemolysis. Methemoglobinemia does not necessarily progress to hemolysis, even if untreated.

FIGURE 127–5. Heinz bodies are particles of denatured hemoglobin, usually attached to the inner surface of the red cell membrane. Xenobiotics that result in the oxidative denaturation of hemoglobin in normal (eg, phenylhydrazine) or glucose-6-phosphate dehydrogenase deficient (primaquine) individuals and unstable hemoglobin mutants are prone to develop these bodies. The Heinz bodies can be identified when blood is mixed with a supravital stain, notably crystal violet. The Heinz bodies appear as purple inclusions. (Reproduced with permission from Lichtman MA, Shafer MS, Felgar RE, Wang N. Lichtman’s Atlas of Hematology, 1st ed. New York: McGraw-Hill, Inc; 2007.)

Numerous cases describe the occurrence of hemolysis after methemoglobinemia. The combined occurrence is reported with dapsone,^{25,53} phenazopyridine,^{21,30,38,77} amyl nitrite,¹⁷ copper sulfate,³⁴ and aniline.^{54,57} These instances of combined syndromes may represent the incidental toxicity of an oxidizing agent at both locations or may represent the depletion of all cellular defenses against oxidants. Currently, it is not possible to predict when hemolysis will occur after methemoglobinemia with any degree of certainty.

CLINICAL MANIFESTATIONS

The clinical manifestations of methemoglobinemia are related to impaired oxygen-carrying capacity and delivery to the tissue. The clinical manifestations of acquired methemoglobinemia are usually more severe than those produced by a corresponding degree of anemia. This discordance occurs because methemoglobin not only decreases the available oxygen-carrying capacity but also increases the affinity of the unaltered hemoglobin for oxygen. This shifts the oxygen hemoglobin dissociation curve to the left, which further impairs oxygen delivery²⁴ (Chap. 29). This effect is attributed to the formation of heme compounds intermediate between normal reduced hemoglobin (all four iron atoms are ferrous) and methemoglobin, in which one or more of the iron moieties are in the ferric state.²⁴ The degree to which this high oxygen affinity hemoglobin reduces oxygen delivery to the tissue from arterial blood is unclear but is clinically significant.¹⁹

Because the symptoms associated with methemoglobinemia are related to impaired oxygen delivery to the tissues, concurrent diseases such as anemia, congestive heart failure, chronic obstructive pulmonary disease, and pneumonia may greatly increase the clinical effects of methemoglobinemia (Fig. 127–6). Predictions of symptoms and recommendations for therapy are based on methemoglobin percentage in previously healthy individuals with normal total hemoglobin concentrations.

FIGURE 127-6. Clinical manifestations of methemoglobinemia depend on the level of methemoglobin and on host factors such as preexisting disease, anemia, and hypoxemia. Five examples of arterial blood gas and cooximeter analyses are presented. (A) Blood gas from a normal individual with 14 g/dL of hemoglobin. Almost all hemoglobin is saturated with oxygen. (B) Blood gas from a patient with cardiopulmonary disease producing cyanosis in which only 9 g/dL of hemoglobin is capable of oxygen transport. (C) Methemoglobin level of 28% in an otherwise normal individual will reduce hemoglobin available for oxygen transport to less than 9 g/dL (~ 4 g/dL of methemoglobin and 1.3 g/dL of high oxygen affinity hemoglobin because of the left shift of the oxyhemoglobin dissociation curve). (D) Same degree of methemoglobin as in C but in a patient with a hemoglobin of 10 g/dL. Only 6 g/dL of hemoglobin would be capable of oxygen transport. (E) Methemoglobinemia and anemia to the same degree as D but in a hypoxic patient.

Cyanosis is a consistent physical finding in patients with substantial methemoglobinemia and is caused by the deeply pigmented color of methemoglobin. Cyanosis typically occurs when just 1.5 g/dL of methemoglobin is present. This represents only 10% conversion of hemoglobin to methemoglobin if the baseline hemoglobin is 15 g/dL. By contrast, 5 g/dL of deoxyhemoglobin (which represents 33% of the total hemoglobin concentration) is needed to produce the same degree of cyanosis from hypoxia (Table 127-3).

TABLE 127-3. Signs and Symptoms Typically Associated with Methemoglobin Levels in Healthy Patients with Normal Hemoglobin Concentrations

<i>Methemoglobin Level (%)</i>	<i>Signs and Symptoms</i>
1–3 (normal)	None
3–15	Possibly none Pulse oximeter reads low SaO ₂ Slate gray cutaneous coloration
15–20	Chocolate brown blood Cyanosis
20–50	Dizziness, syncope Dyspnea Exercise intolerance Fatigue Headache Weakness
50–70	Central nervous system depression Coma Dysrhythmias Metabolic acidosis Seizures Tachypnea
> 70	Death Grave hypoxic symptoms

The cyanosis associated with methemoglobinemia is both peripheral and central. Patients often appear in less distress or less ill than patients with the same degree of cyanosis secondary to cardiopulmonary causes.

The symptoms of methemoglobinemia are determined not only by the absolute percent of methemoglobin but also by its rates of formation and elimination. A percentage of methemoglobin that may be clinically benign when caused by hereditary defects or maintained chronically likely will produce more severe signs when acutely acquired. Healthy subjects lack the compensatory mechanisms that develop over a lifetime in individuals with hereditary compromise, such as erythrocytosis and increased 2,3-bisphosphoglyceric acid.

DIAGNOSTIC TESTING

For an individual in whom methemoglobinemia is suspected, a source for the oxidant stress should be sought. Arterial blood gas sampling may reveal blood with a characteristic chocolate brown color. However, in patients who are clinically stable and not in need of an arterial puncture, a venous blood gas will be accurate in demonstrating the methemoglobin level. The arterial PO₂ should be normal, reflecting the adequacy of pulmonary function to deliver dissolved oxygen to the blood. However, arterial PO₂ does not directly measure the hemoglobin oxygen saturation (SaO₂) or oxygen content of the blood. When the partial pressure of oxygen is known and oxyhemoglobin and deoxyhemoglobin are the only species of hemoglobin, oxygen saturation can be calculated accurately from the arterial blood gas. If, however, other hemoglobins are present, such as methemoglobin, sulfhemoglobin, or carboxyhemoglobin, then the fractional saturation of the different hemoglobin species must be determined by cooximetry in the laboratory.

The cooximeter is a spectrophotometer that identifies the absorptive characteristics of several hemoglobin species at different wavelengths. Because oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin all have different absorptions at the different measuring points of the cooximeter, their proportions and concentrations can be determined. Some newer cooximeters have an expanded spectrum at which they read and are also able to read fetal hemoglobin and sulfhemoglobin.¹¹³

The pulse oximeter applied to a patient's finger at the bedside was developed to estimate oxygen saturation trends in critically ill patients. The device takes advantage of the unique absorptive characteristics of oxyhemoglobin and deoxyhemoglobin and the different concentrations of these two hemoglobin species during different phases of the pulse. Each manufacturer has calibrated its oximeter using volunteers breathing progressively increasing hypoxic gas mixtures in the absence of a dysmethemoglobinemia.^{88,100,106} In other words, the oxygen saturation values displayed on the pulse oximeter are derived independently by each manufacturer, which develops a formula using their own hardware and sensor. The manufacturer then compares this value with a set of validation data derived from their own experimental population.

Most pulse oximeters in use today use two different wavelengths to determine O₂ saturation and the manufacturers do not provide validation data for situations where any dyshemoglobin is present. These manufacturers disclaim accuracy under such circumstances. Similar to cooximetry, the dual-wavelength pulse oximeter reads absorbance of light at wavelengths of 660 and 940 nm, which are selected to efficiently separate oxyhemoglobin and deoxyhemoglobin. However, methemoglobin absorption at these wavelengths is greater than that of either oxyhemoglobin or deoxyhemoglobin.^{8,71} Therefore, when methemoglobin is present, the readings become inaccurate. The degree of inaccuracy is unique for each brand of instrument and may be influenced by signal quality, skin temperature, refractive error induced by blood cells, and other factors (eg, finger thickness and perfusion).⁹⁰ Hemoglobin variants—of which thousands exist—have been shown to interfere with pulse oximetry accuracy as well.¹⁰⁵

In the dog model, the pulse oximeter oxygen saturation (SpO₂) values decrease with increasing methemoglobin levels. This decrease in SpO₂ is not exactly proportional to the percentage of methemoglobin. However, the pulse oximeter overestimates the level of actual oxygen saturation. For example, in a case in which the methemoglobin level measured in the blood using a cooximeter was 20%, the pulse oximeter indicated an SpO₂ of 90%.^{9,104} However, as the methemoglobin concentration approached 30%, the pulse oximeter saturation values decreased to about 85% and then leveled off, regardless of how much higher the methemoglobin level became.^{9,104}

From our experience and that of others,^{42,89} in humans, much lower levels of oxygen saturation (SpO₂) than 85% can be displayed by pulse oximetry when methemoglobin levels increase above 30%.⁵² These differences result from variations in the way different model pulse oximeters deal with methemoglobin interference.^{88,89} Therefore, health care professionals must understand how the particular pulse oximeter measures oxygen saturation when methemoglobin levels are elevated and recognize that cooximetry determination is needed when methemoglobinemia is suspected.

Although the pulse oximeter reading in patients with methemoglobinemia may not be as accurate as desired, it may be helpful when it is compared with that of the arterial blood gas: if there is a difference between the measured oxyhemoglobin saturation of the pulse oximeter (SaO₂) and the calculated oxyhemoglobin saturation of the arterial blood gas (SpO₂), then a “saturation gap” exists. The calculated SaO₂ of the blood gas will be greater than the measured SpO₂ if methemoglobin is present (Table 127–4).

TABLE 127–4. Hemoglobin Oxygenation Analysis

Measuring Device	Source	What Is Measured	How Data Are Expressed	Benefits	Pitfalls	Insight
Blood gas analyzer	Blood	Partial pressure of dissolved oxygen in whole blood	PO ₂	Also gives information about pH and PCO ₂	Calculates SaO ₂ from the partial pressure of oxygen in blood; inaccurate if forms of Hb other than OxyHb and DeoxyHb are present	An abnormal Hb form may exist if gap exists between ABG and pulse oximeter
Cooximeter	Blood	Directly measures absorptive characteristics of oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin at different wavelength bands in whole blood	SaO ₂ , %MethHb, %CoHb, %OxyHb, %DeoxyHb	Directly measures hemoglobin species	Provides data on hemoglobin only; most instruments will not measure sulfhemoglobin, HbM, and some other forms of Hb	Most accurate method of determining the oxygen content of blood
Pulse oximeter	Monitor sensor on patient	Absorptive characteristics of oxyhemoglobin in pulsatile blood assuming the presence of only OxyHb and DeoxyHb in vivo	SpO ₂	Moment-to-moment bedside data	Inaccurate data if interfering substances are present (methemoglobin, sulfhemoglobin, carboxyhemoglobin, methylene blue)	Maximum depression, 75%–85% regardless of how much methemoglobin is present

ABG = arterial blood gas; Hb = hemoglobin; HbM = hemoglobin M; SaO₂ = hemoglobin oxygen saturation; SpO₂ = pulse oximeter oxygen saturation.

Several manufacturers have developed pulse oximeters that read multiple wavelengths to identify other hemoglobin species such as methemoglobin, carboxyhemoglobin, and total hemoglobin concentration.^{26,27,98,112} Validation studies using human volunteers with these new pulse oximeters suggest that the accuracy for detecting methemoglobin is acceptable.^{26,27} Volunteers breathing room air given sodium nitrite at 75% of the cyanide kit recommended dose developed methemoglobinemia that was detected by the multiwavelength device. There was spuriously low SpO₂ recorded.^{26,27} However, this may not be an issue if it alerts the clinician to a potential problem. Certainly, in a situation where xenobiotics known to produce methemoglobinemia are being used such as in the endoscopy or bronchoscopy suite to determine changes from baseline in methemoglobin.

Methemoglobin produces a color change that can be observed when a drop of blood is placed on absorbant white paper. In one study when various concentrations of methemoglobin from 10% to 100% were produced in vitro and a drop of each concentration placed on a white background a color chart was developed that could reliably be used to predict methemoglobin concentrations.⁹⁹ In situations where laboratory evaluation is limited this may be useful.

MANAGEMENT

For most patients with mild methemoglobinemia of approximately 10%, no therapy is necessary other than withdrawal of the offending xenobiotic because reduction of the methemoglobin will occur by normal reversion mechanisms (NADH methemoglobin reductase). However, in some patients, even small elevations of methemoglobin should be considered problematic because they suggest the individual is at a point where further oxidant stress may cause methemoglobin levels to increase. An individual receiving dapsone with a small elevation of methemoglobin level may be more susceptible to clinically significant methemoglobinemia if challenged with a benzocaine-containing anesthetic or an increase in dapsone dose. In the clinical setting, continued absorption, prolonged half-life, and toxic intermediate metabolites may prolong methemoglobinemia. Patients should be examined carefully for signs of physiologic stress related to decreased oxygen delivery to the tissue (Fig. 127–7). Obviously, changes in mental status or ischemic chest pain necessitate immediate treatment, but subtle changes in behavior or inattentiveness may be signs of global hypoxia and should be treated. Patients with abnormal vital signs tachycardia and tachypnea or an elevated lactate concentration thought to be caused by tissue hypoxia or the functional anemia of methemoglobinemia should be treated aggressively. A mildly elevated methemoglobin level alone generally is not an adequate indication of need for therapy but as levels reach 30% to 40% almost all patients should be treated.

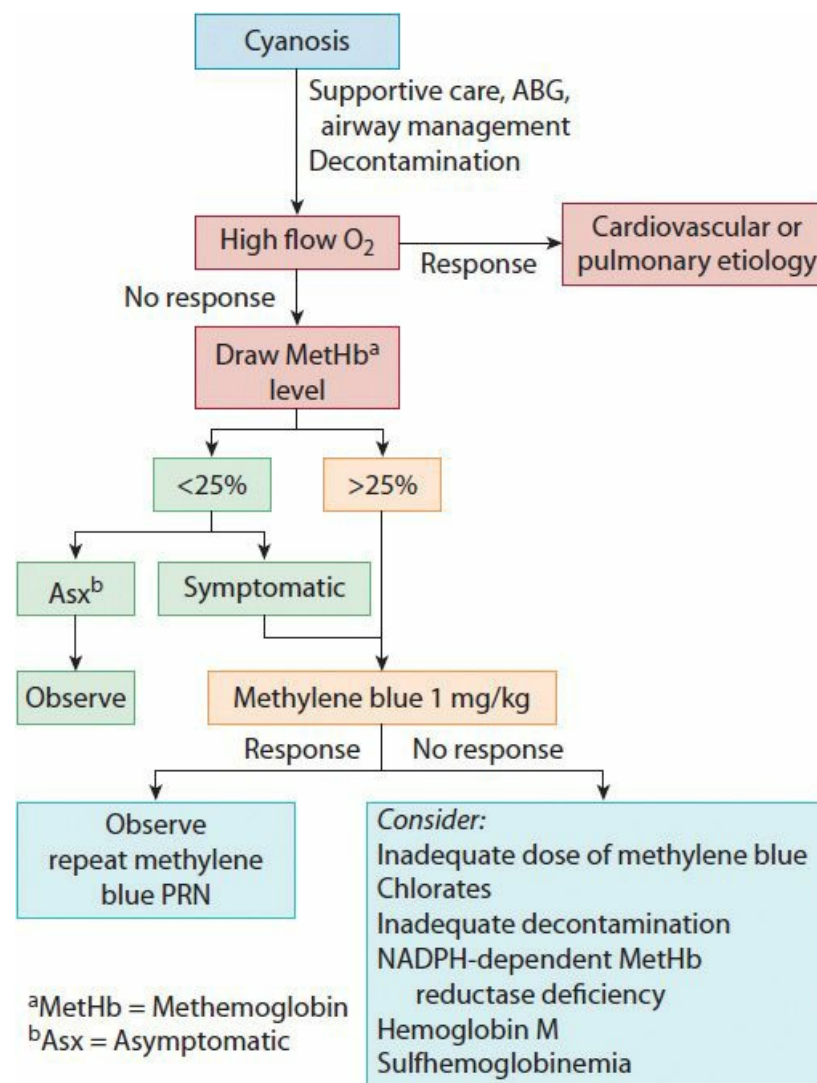

FIGURE 127–7. Toxicologic assessment of a cyanotic patient.

The most widely accepted treatment of methemoglobinemia is administration of 1 to 2 mg/kg body weight of methylene blue infused intravenously (IV) over 5 minutes. This is 0.1 to 0.2 mL/kg of 1% solution. The use of a slow 5-minute infusion helps prevent painful local responses from rapid infusion. A painful reaction can be minimized by flushing the IV rapidly with a bolus of at least 15 to 30 mL of fluid following the infusion. Clinical improvement should be noted within minutes of methylene blue administration. If cyanosis has not disappeared within one hour of the infusion, then a second

dose should be given and other factors considered (Fig. 127–7). Methylene blue causes a transient decrease in the pulse oximetry reading because its blue color has excellent absorbance at 660 nm.^{62,68}

The use of methylene blue in patients with G-6-PD deficiency is controversial. Deficiency of this enzyme is an estimated 200 million people worldwide. Its incidence in the United States is highest among African Americans (11%),¹⁰ among whom the disease has different degrees of severity. For this reason, G-6-PD–deficient patients were once excluded from most treatment protocols because methylene blue is a mild oxidant and case reports have suggested the toxicity of methylene blue. However, because of the lack of immediate availability of G-6-PD testing, most patients who need treatment receive methylene blue therapy before their G-6-PD status is known. Although many patients with G-6-PD deficiency undoubtedly have been treated unknowingly, few case reports of toxicity have been described.

Even the authors of the review most frequently cited as a rationale for withholding methylene blue treatment were unsure whether the methylene blue given to their G-6-PD–deficient patient produced hemolysis⁹⁴; the dose of methylene blue given to the patient was small, and the patient had taken other xenobiotics capable of producing hemolysis. Patients with G-6-PD deficiency have variable activity of the enzyme and manifest different degrees of disease in response to oxidant stress. For all of these reasons, the judicious use of methylene blue is warranted in most patients with G-6-PD deficiency and symptomatic methemoglobinemia.

If methylene blue treatment fails to significantly reverse methemoglobinemia, a number of possibilities should be considered. The cause of the oxidant stress may not have been identified and adequately removed, allowing for continuing oxidation. In such situations, decontamination of the gut and skin cleansing must be assured. Additional doses of methylene blue are also indicated. Patients who have sulfhemoglobinemia, or are deficient in NADPH methemoglobin reductase, may not improve after methylene blue therapy (Antidotes in Depth: A42).

Theoretically, exchange transfusion or hyperbaric oxygen (HBO) may be beneficial when methylene blue is ineffective. Both interventions are time consuming and costly, but HBO allows the dissolved oxygen time to protect the patient while endogenous methemoglobin reduction occurs. Ascorbic acid is not indicated in the management of acquired methemoglobinemia if methylene blue is unavailable because the rate at which ascorbic acid reduces methemoglobin is considerably slower than the rate of normal intrinsic mechanisms.¹⁴ Methylene blue has no therapeutic benefit in the presence of sulfhemoglobinemia.⁸⁶

Treatment with dapsone deserves special consideration because of its tendency to produce prolonged methemoglobinemia. N-hydroxylation of dapsone to its hydroxylamine metabolite by a cytochrome P450–mediated reaction is partly responsible for methemoglobin formation in both therapeutic and overdose situations. Both the parent compound and its metabolites are oxidants with long half-lives. Cimetidine is a competitive inhibitor in the cytochrome P450 metabolic pathway and reduces methemoglobin concentrations during therapeutic dosing because less dapsone will be metabolized by the route.⁹¹ In situations of overdose, cimetidine may exert some protective effects and should be used with methylene blue. When dapsone is therapeutically indicated but low levels of methemoglobin are found, cimetidine should be considered as a method for reducing oxidant stress.

SULFHEMOGLOBIN

Sulfhemoglobin is a variant of hemoglobin in which a sulfur atom is incorporated into the heme molecule but is not attached to iron. The exact location of the sulfur atom in the porphyrin ring is unclear. Sulfhemoglobin is a darker pigment than methemoglobin, producing cyanosis when only 0.5 g/dL of blood is affected. The cyanosis produced is similar to that produced by methemoglobinemia. Sulfhemoglobin also reduces the oxygen saturation determined by the pulse oximeter^{2,80} and is characterized in the laboratory by its spectrophotometric appearance and its lack of reaction when cyanide is added to the mixture. Cyanide does not react with sulfhemoglobin but does react with methemoglobin, forming cyanomethemoglobin, which has no adsorption at the spectrums tested. By contrast, the methemoglobin absorption peak will no longer be present after the addition of cyanide. Using conventional cooximetry, sulfhemoglobin is misidentified as methemoglobin. However, the addition of cyanide to the blood sample eliminates the methemoglobin peak (through conversion to cyanomethemoglobin) but not the methemoglobin peak caused by sulfhemoglobin. This technique is not routinely done in the clinical laboratory, and the diagnosis often is made based on the patient's failure to improve with methylene blue.^{2,64,70,80} In the laboratory, isoelectric focusing techniques further define sulfhemoglobin.

Sulfhemoglobin is an extremely stable compound that is eliminated only when red blood cells are removed naturally from circulation. Although the oxygen-carrying capacity of hemoglobin is reduced by sulfhemoglobinemia, unlike methemoglobinemia there is a decreased affinity for oxygen in the remaining “unaltered” hemoglobin. The oxyhemoglobin dissociation curve is shifted to the right. This makes oxygen more available to the tissues. This phenomenon reduces the clinical effect of sulfhemoglobin in the tissues.

Sulfhemoglobin can be produced experimentally in vitro by the action of hydrogen sulfide on hemoglobin and was produced in dogs fed elemental sulfur.⁸⁶ A number of xenobiotics induce sulfhemoglobin in humans, including acetanilid, phenacetin, nitrates, trinitrotoluene, and sulfur compounds. Most of the xenobiotics that produce methemoglobinemia are

reported in various degrees to produce sulfhemoglobinemia. Sulfhemoglobinemia is also recognized in individuals with chronic constipation and in those who abuse laxatives.⁸⁶

Sulfhemoglobinemia usually requires no therapy other than withdrawal of the offending xenobiotic. It appears that patients come to the attention of clinicians earlier because sulfhemoglobinemia produces more cyanosis than does methemoglobinemia. There is no antidote for sulfhemoglobinemia because it results from an irreversible chemical bond that occurs within the hemoglobin molecule. Exchange transfusion would lower the sulfhemoglobin concentration, but this approach usually is unnecessary.

SUMMARY

- Methemoglobinemia is defined as an abnormal level of methemoglobin above 1%.
- Methemoglobinemia is clinically identified by cyanosis without cardiovascular causes, a normal PO₂ on blood gas analysis, chocolate colored blood, and elevated methemoglobin level on cooximetry.
- Symptoms are usually milder than the appearance of the cyanosis would suggest and can be as minimal as mild fatigue and exertional dyspnea to seizures and central nervous system depression depending on degree and coexisting disease.
- Indications for methylene blue therapy include symptoms of cardiovascular or respiratory distress, any central nervous system symptoms or findings, and metabolic acidosis. Patients with levels above 30% methemoglobin should be considered as candidates for therapy.
- Patients with low methemoglobin levels should be considered to be under oxidant stress and at risk for more serious methemoglobinemia if oxidant stressors persist or increase in their environment.
- Methemoglobinemia should be considered to be a disease state sometimes caused by an acute, overwhelming oxidant protective mechanism of the host by an oxidant or more commonly and, importantly, as a final clinical manifestation of multiple oxidant stressors.
- Multiwavelength pulse oximeters are becoming more accurate and should be used routinely to monitor patients undergoing procedures where oxidants, such as benzocaine and lidocaine, are being used.

A42 ANTIDOTES IN DEPTH

Methylene Blue

Mary Ann Howland

INTRODUCTION

Methylene blue is an extremely effective antidote for acquired methemoglobinemia. Methylene blue has other actions, including the inhibition of nitric oxide synthase and guanylyl cyclase, and the inhibition of the generation of oxygen free radicals. These actions may explain the beneficial effects of methylene blue in the treatment of refractory hypotension, hepatopulmonary syndrome, treatment of priapism, modulation of streptozocin-induced insulin deficiency, prevention and treatment of ifosfamide-induced encephalopathy, in the treatment of sepsis, and the reduction of the development of postsurgical peritoneal adhesions.^{15,16,21,25,34,44,52,59}

HISTORY

Methylene blue was initially recommended as an intestinal and urinary antiseptic and subsequently recognized as a weak antimalarial.²⁰ In 1933, Williams and Challis successfully used methylene blue for treatment of aniline-induced methemoglobinemia.⁶⁴

PHARMACOLOGY

Chemistry

Methylene blue is tetramethylthionine chloride,²⁰ a basic thiazine dye with a molecular weight of 319 Da. It is deep blue in the oxidized state and colorless when reduced to leucomethylene blue.

Mechanisms of Action

Methylene blue is an oxidizing agent, which, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH methemoglobin reductase, is reduced to leucomethylene blue (Fig. 127–4). Leucomethylene blue then becomes available to reduce methemoglobin to hemoglobin.^{9,20,60} Reduction of methemoglobin via this NADPH pathway is limited under normal circumstances. However, in the presence of methylene blue, the role of the NADPH pathway is dramatically increased and becomes the most efficient means of methemoglobin reduction.

Recently, attention has focused on the ability of methylene blue to reverse refractory hypotension due to many causes including drug overdose, vasoplegia, and sepsis. Methylene blue inhibits nitric oxide synthase and guanylyl cyclase in vascular smooth muscle. This reduces the amount and effect of nitric oxide. Systemic vascular resistance and cardiac output increase, and the sensitivity of adrenergic receptors to sympathomimetics is enhanced.^{12,14,36,27,38,63}

Pharmacokinetics

The pharmacokinetics of methylene blue were studied in animals and human volunteers following intravenous (IV) and oral administration of 100 mg.^{9–11,45} Methylene blue exhibits complex pharmacokinetics consistent with extensive distribution into deep compartments, followed by a slower terminal elimination, with a half-life of 5.25 hours. Peak concentrations after oral administration were reached in 1 to 2 hours, but were only approximately 80 to 90 nmol/L, as opposed to 8000 to 9000 nmol/L following IV administration. The substantial differences in whole blood concentrations achieved by these routes of administration can be attributed to extensive first-pass organ distribution into the intestinal wall and liver, following oral administration.³⁵ Total urinary excretion at 24 hours accounts for 28.6% of the drug following IV administration, compared with 18.5% after oral administration. In both instances, one third was in the leucomethylene blue form.

Pharmacodynamics

The onset of action of methylene blue for the reversal of methemoglobin is often within minutes. Maximum effects usually occur by 30 minutes.²³

ROLE IN XENOBIOTIC-INDUCED METHEMOGLOBINEMIA

Methylene blue is indicated in patients with symptomatic methemoglobinemia. This usually occurs at methemoglobin levels greater than 20%, but may occur at lower levels in anemic patients or those with cardiovascular, pulmonary, or central nervous system compromise.

Historically, sulfanilamide induced methemoglobinemia was reversed by methylene blue in IV doses of 1 to 2 mg/kg or oral doses of 65 to 130 mg, given every 4 hours.^{22,61} With these regimens, a very rapid fall in methemoglobin was accompanied by disappearance of cyanosis. Subsequent investigations confirmed the effectiveness and safety of IV doses of 1 to 2 mg/kg in reversing the methemoglobinemia produced by sulfanilamide,⁶¹ aniline dye,¹³ silver nitrate, benzocaine, nitrites, phenazopyridine, and other xenobiotics.^{55,58}

The risk-to-benefit ratio of using methylene blue in a patient for methemoglobinemia must always be weighed as with any other drug. In this case, the benefit of using methylene blue for a patient with significant methemoglobinemia will almost always outweigh the risk of possibly precipitating serotonin toxicity in a patient taking an SSRI (refer to Adverse Events).

Methylene blue is ineffective in the treatment of sulfhemoglobinemia ([Chap. 127](#)).

ROLE IN HYPOTENSION

Hypotension refractory to vasopressors occurs in the setting of sepsis, vasoplegia, and drug ingestion. Methylene blue has successfully reversed the low systemic vascular resistance in a few case studies and case reports.^{12,14,27,28,32,35,36,38,47,63}

ADVERSE EFFECTS AND SAFETY ISSUES

Reports of the paradoxical induction of methemoglobinemia by methylene blue suggest an equilibrium between the direct oxidization of hemoglobin to methemoglobin by methylene blue and its ability (through the NADPH and NADPH methemoglobin reductase pathway, and leukomethylene blue production) to reduce methemoglobin to hemoglobin.^{4,5} Methylene blue does not produce methemoglobin at doses of 1 to 2 mg/kg. The equilibrium seems to favor the reducing properties of methylene blue, unless excessively large doses of methylene blue are administered,^{3,19,62} or the NADPH methemoglobin reductase system is abnormal. This equilibrium constant may vary substantially, as 20 mg/kg IV in dogs and 65 mg/kg intraperitoneally in rats failed to produce methemoglobinemia.⁵⁴ In early studies, 50 to 100 mL of a 1% concentration (500–1000 mg) of methylene blue was used intravenously in volunteers³⁹ as well as in the treatment of patients with aniline dye induced methemoglobinemia.⁶⁴ In these studies, methemoglobin levels, measured when symptoms were most pronounced, were approximately 1.0 g/dL (0.4%–8.3% of total hemoglobin), and unlikely to be solely responsible for the adverse effects demonstrated. Other consequential adverse effects included shortness of breath, tachypnea, chest discomfort, a burning sensation of the mouth and stomach, initial bluish tinged skin and mucous membranes, paresthesias, restlessness, apprehension, tremors, nausea and vomiting, dysuria, and excitation. Urine and vomitus may appear blue in color. These limited studies led to the recommendation to avoid doses higher than 7 mg/kg.

In high doses, methylene blue can induce acute hemolytic anemia independent of the presence of methemoglobinemia.^{19,33} In dose–response studies in glucose-6-phosphate dehydrogenase (G6PD) deficient homozygous African American men, daily doses of 390 to 780 mg (5.5–11 mg/kg) of methylene blue produced hemolysis,³¹ which was comparable with the results following exposure to 15 mg of primaquine base.³¹ Because of the sensitivity of neonates (hemoglobin F and diminished NADH reductase) to these risks, the smallest effective dose of methylene blue should be used.^{24,30} Because any oxidizing agent can independently induce a Heinz body hemolytic anemia, the specific contribution of methylene blue often is difficult to elucidate.³⁰

Since methylene blue is a dye it will alter pulse oximeter readings.⁷ Large doses may interfere with the ability to detect a clinical decrease in cyanosis; therefore, repeat cooximeter measurements and arterial blood gas analysis should be used in conjunction with clinical findings to evaluate improvement.

Intraamniotic injection of methylene blue may result in a number of adverse effects, including infants born with blue skin (with resultant inaccurate pulse oximetry readings),⁴³ methemoglobinemia, hemolysis, phototoxic skin reactions,⁴⁶ or intestinal obstruction.^{7,8,29,33,37,42,49,57} One infant exposed in utero at 5.5 weeks was normal at birth.²⁹ An excessive dose of enterally administered methylene blue that subsequently leaked into the peritoneum of a premature neonate most likely was

responsible for a hemolytic anemia appearing 3 days later.¹

Methylene blue leads to a bluish-green discoloration of the urine, and can potentially cause dysuria.⁴⁸ IV methylene blue is irritating and exceedingly painful. It may cause local tissue damage even in the absence of extravasation.⁴⁹ Subcutaneous and intrathecal administrations are contraindicated.⁴⁹

Two recent reviews reveal an association between an encephalopathy and the use of methylene blue for localization of parathyroid tumors in women on serotonin reuptake inhibitors.^{41,56} Five out of 132 patients in the first review developed one or more of the following: confusion, expressive aphasia, lethargy, and vertigo, which lasted from 2 to 3 days. The second review detailed seven patients with signs and symptoms consistent with serotonin toxicity. It should be noted that these patients usually received 3 to 5 mg/kg of methylene blue as a continuous infusion over 1 hour. A subsequent in vitro study documented the ability of methylene blue to competitively bind to monoamine oxidase A, raising the possibility that methylene blue might interact with serotonergic xenobiotics by acting as a monoamine oxidase inhibitor.⁵⁰ Two recent reviews also conclude that methylene blue has the potential to interact with drugs that elevate serotonin to cause serotonin excess and toxicity.^{18,40}

High doses of methylene blue (7 mg/kg) have the potential to decrease splanchnic blood flow in the setting of septic shock.²⁸

One author suggests that methylene blue directly inactivates lactic acid giving a potentially false impression of improved perfusion.¹⁴ However, this finding needs to be confirmed.

Use in Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Methylene blue is frequently hypothesized to be ineffective in reversing methemoglobinemia in patients with G6PD deficiency⁴¹ because G6PD is essential for generation of NADPH (Chap. 23). Without NADPH, methylene blue cannot reduce methemoglobin. However, G6PD deficiency is an X-linked hereditary deficiency with more than 400 variants. The red cells containing the more common G6PD A⁻ variant found in 11% of African Americans retain 10% residual activity, mostly in younger erythrocytes and reticulocytes. By contrast, the enzyme is barely detectable in those of Mediterranean descent who have inherited the defect. Therefore, it is impossible to predict before the use of methylene blue which persons will or will not respond, and to what extent. Currently, it appears that most individuals have adequate G6PD and express deficiency states in relative terms. This variable expression of their deficiency allows an effective response to most oxidant stresses. In addition, in theory, normal cells might convert methylene blue to leukomethylene blue, which might diffuse into G6PD deficient cells and effectively reduce methemoglobin to hemoglobin.²

Before assuming that G6PD deficiency is responsible for a continued elevation of methemoglobin levels despite administration of methylene blue, ongoing xenobiotic absorption and or continued methemoglobin production must be excluded. On the other hand, when therapeutic doses of methylene blue fail to have an impact on the methemoglobin concentration, the possibility of G6PD deficiency should be considered, and further doses of methylene blue should not be administered because of the risk of methylene blue induced hemolysis. In these cases, exchange transfusion and hyperbaric oxygen are potential alternatives for treating methemoglobinemia (Chap. 127).

PREGNANCY AND LACTATION

Methylene blue is a category X drug in pregnancy. IV methylene blue has led to fetal abnormalities, including atresia of the ileum and jejunum, ileal occlusions, hemolytic anemia, hyperbilirubinemia, and methemoglobinemia when used via intraamniotic injection. Human data suggest developmental toxicity when used in the second and third trimesters.⁶

There are no data available on lactation, but it is not likely to present a danger to the nursing infant.⁶

DOSING AND ADMINISTRATION

In most cases, a dose of 1 to 2 mg/kg given IV over 5 minutes, followed immediately by a fluid flush of 15 to 30 mL to minimize local pain, is both effective and relatively safe. In neonates, 0.3 to 1 mg/kg doses often are effective.^{17,26} The onset of action is rapid, and maximal effects usually occur within 30 minutes.

Repetitive dosing of methylene blue may be required in conjunction with efforts to decontaminate the gastrointestinal tract when there is continued absorption or slow elimination of the xenobiotic producing the methemoglobinemia, such as with dapsone.

Intraosseous administration of 0.3 mL of 1% solution (1 mg/kg) of methylene blue over 3 to 5 minutes into the anterior tibia of a 6 week-old infant was well tolerated.^{24,43} The dose of methylene blue for refractory hypotension is not established. Doses of 1 to 3 mg/kg increase systemic vascular resistance and mean arterial pressure and improve tissue oxygenation.²⁴ Although doses of 7 mg/kg may produce further increases in mean arterial pressure, this result is at the

expense of decreasing splanchnic blood flow.²⁸

FORMULATION AND ACQUISITION

Methylene blue is available in 10 mL vials of a 1% solution for injection, containing 10 mg/mL.

SUMMARY

- Methylene blue is an effective reducing agent for patients with acquired methemoglobinemia.
- When used in the proper dose, the onset of action for methylene blue is rapid and its adverse reactions are limited.
- Repeat doses often are required when methemoglobin-producing drugs with a long duration of effect, such as dapsone, are ingested.
